Geneva

### THE AUTHORS

**Frank Fenner, M.D.**, has been a professor at the Australian National University since 1949. Since 1969 he has been a member of the WHO Informal Group on Monkeypox and Related Viruses and of various WHO committees on orthopoxviruses, and in 1978-1979 was Chairman of the Global Commission for the Certification of Smallpox Eradication. He is currently a Visiting Fellow in the John Curtin School of Medical Research, Australian National University, Canberra.

**Isao Arita, M.D.**, worked for the smallpox eradication programme in western Africa in 1962-1963 as a member of the staff of the WHO Regional Office for Africa. In 1964 he was transferred to WHO Headquarters in Geneva, and in 1966 he joined the Smallpox Eradication unit, of which he was Chief from 1977 until 1984. He is now Director of the Kumamoto National Hospital in Japan and a member of the advisory group on international health of the Ministry of Health and Welfare of Japan.

**Donald Ainslie Henderson, M.D.**, while at the Communicable Disease Center in the USA, was responsible in 1965-1966 for the planning of the western and central African smallpox eradication-measles control programme, conducted with the support of the United States Agency for International Development. From 1966 to 1977 he was Chief of the Smallpox Eradication unit in the World Health Organization. In 1977 he became Dean of the Johns Hopkins School of Hygiene and Public Health, Baltimore, Maryland, USA, and Professor of Epidemiology and International Health. He was a member of the Global Commission for the Certification of Smallpox Eradication.

**Zdeněk Ježek, M.D.**, joined the field staff of the Intensified Smallpox Eradication Programme in 1972, working first with the WHO Smallpox Eradication and Epidemiological Advisory Team in the WHO South-East Asia Region and later in Somalia. He joined the Smallpox Eradication unit at WHO Headquarters in 1980 and became Chief of the unit in 1985.

**Ivan Danilovich Ladnyi, M.D.**, served as a WHO Inter-country Adviser on smallpox eradication in Africa from 1965 to 1971. From 1976 to 1983 he was Assistant Director-General of the World Health Organization, responsible for communicable and parasitic diseases. He was then Deputy Director of the All-Union Institute of Medical Information of the Ministry of Health of the USSR from 1983 until his death in 1987.

The authors alone are responsible for the views expressed in this publication.

# Foreword

For more than three thousand years, smallpox was a major scourge of mankind, spreading across the world as new centres of population became established and grew in size. Because of its high fatality rate, it was universally feared; in the towns and cities of Asia and Europe where records were kept, it caused on average 10% of all deaths each year. As early as the tenth century, Chinese and Indian sages had discovered a method that provided some protection against this terrible scourge, albeit one which often resulted in serious illness and some loss of life. This was the inoculation of smallpox virus from scabs—variolation—a practice that was taken up in a number of countries but seldom widely applied. Then in 1796 came one of the seminal discoveries of medicine—the demonstration by experiment that a harmless virus obtained from cows could protect man against smallpox. Edward Jenner, an English country doctor, had discovered vaccination—a practice which was rapidly disseminated throughout the world. It resulted in a marked decrease in the toll of smallpox in the industrialized countries, but the disease continued almost unabated in Africa, Asia and Latin America.

The World Health Organization was established in 1948 and from its inception successive World Health Assemblies urged Member States to take all measures to control smallpox. In 1953 the first Director-General, Dr Brock Chisholm, made an unsuccessful attempt to persuade the World Health Assembly to undertake a global smallpox eradication programme. Five years later a Soviet delegate to the Assembly, Dr Viktor Zhdanov, persuaded the Organization to accept responsibility for a global eradication programme. But only minimal funds were provided, and although by 1967 the disease was eliminated from some thirty countries in Asia, Africa and South America, the hard core of the problem—the Indian subcontinent and most countries in sub-Saharan Africa—was largely unaffected.

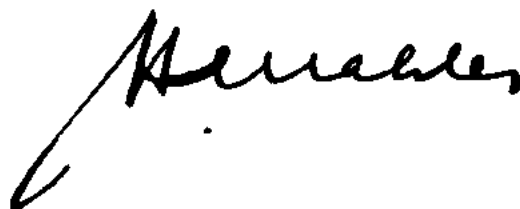

In 1966 the World Health Assembly decided that this situation was intolerable, and established an Intensified Smallpox Eradication Programme, with an annual allocation of \$2.4 million from the WHO regular budget and the declared goal of global eradication within 10 years. Thanks to the efforts of numberless national health staff in the endemic countries, the enthusiastic devotion of international workers, and the masterly coordination of the effort by the WHO Smallpox Eradication unit, the goal of global eradication was achieved in just over ten years.

Simultaneously, a sustained effort was made to demonstrate to the public and the international health community that eradication had indeed been achieved, by a carefully orchestrated certification programme planned and coordinated by the World Health Organization. The result was that on 8 May 1980 the Thirty-third World Health Assembly adopted a resolution declaring that smallpox had been eradicated globally. In another resolution it endorsed 19 recommendations covering all aspects of the post-smallpox-eradication era, including the cessation of vaccination of the public and of international travellers. Despite intensive surveillance, no case of endemic smallpox has been detected anywhere in the world since the last case in Somalia in October 1977.

The Thirty-third World Health Assembly recommended that this unique accomplishment should be properly recorded; this book is the result. Written by five men who were intimately associated with various aspects of the eradication and certification programmes, and subject to detailed review by many of their colleagues

in the eradication campaign, it provides a comprehensive description of a formerly cosmopolitan and lethal disease that man has now eradicated, forever, and of the programme in some eighty countries in Africa, Asia and South America that led to this achievement. The major part of the book recounts the saga of eradication in the ancient strongholds of the disease—Africa, the Indian subcontinent and other parts of Asia. Also included are descriptions of other poxvirus infections of man, and a detailed description of a new, generalized orthopoxvirus disease of man, human monkeypox, discovered during the smallpox eradication programme. The book concludes with an overview of the lessons learnt during the programme—lessons that have already been applied by the World Health Organization to a variety of other programmes designed to lighten the burden of human illness, from the Expanded Programme on Immunization to the new efforts on AIDS.

The World Health Organization, and I, as its Director-General, are proud of this signal achievement in preventive medicine, and proud of the book in which it is described, with its wealth of detail and colour plates, figures, maps and graphs, that records for posterity just what this extinct disease was like and describes in graphic terms the problems and successes of the Intensified Smallpox Eradication Programme.

A handwritten signature in black ink, appearing to read 'H. Mahler', with a long, sweeping underline that extends to the left.

*H. Mahler, M.D.  
Director-General*

# Preface

The world's last naturally occurring case of smallpox developed illness in Somalia late in October 1977; the last case, which was associated with a laboratory infection, occurred in England in September 1978. Following an extensive programme to verify the absence of the disease, the Thirty-third World Health Assembly in May 1980 adopted a resolution accepting the report of the Global Commission for the Certification of Smallpox Eradication, and affirming its belief that this once-universal disease had been eradicated world-wide. In the resolution, the Health Assembly requested "the Director-General to ensure the production, within a reasonable period of time, of appropriate publications describing smallpox and its eradication, in order to preserve the unique historical experience of eradication and thereby contribute to the development of other health programmes". This book, published by the World Health Organization, responds to this request. The authors, all of whom were personally involved in the programme's execution, are, however, entirely responsible for the opinions expressed.

Preparation of the book began in 1980 and was completed in 1987. It was a truly collaborative effort, and each of the authors reviewed and commented on all chapters at various stages of their preparation. Dr Fenner was responsible for the overall organization of the book, the reference lists and the indexes, and wrote Chapters 1-6, 8, 29 and 30. Dr Henderson wrote Chapters 9, 10, 12-22 and 31, assisted by Dr Ježek, who assembled and drafted basic material from the WHO Smallpox Archives and elsewhere. Dr Arita prepared the drafts of Chapters 7, 11 and 23-28 for further editing by Dr Fenner.

The four authors just named wish to pay special tribute to their co-author, Dr Ivan D. Ladnyi, whose tragic death in March 1987 prevented him from contributing, to the later stages of the preparation of this book, the full wealth of his knowledge and experience of the Intensified Smallpox Eradication Programme. His experience was especially valuable as he had both participated actively in the field work in Africa and provided staunch support and leadership in his later position as Assistant Director-General of the World Health Organization.

In addition to review of each chapter by each of the authors, 78 other persons, who were experts in an appropriate scientific field or who had personal knowledge of a particular eradication or certification programme, commented on various chapters when they were in draft form. Their names and affiliations are listed in the Acknowledgements.

The Intensified Smallpox Eradication Programme, the description of which is the main focus of this book, involved many people, in many parts of the world. Its successful prosecution depended on a variety of different activities, ranging from field work to administration through laboratory studies and fund-raising. We decided that the book would be most instructive if it incorporated the whole of this spectrum, and this we have endeavoured to reflect. For completeness, we have also provided a full account of the clinical and epidemiological features of the disease, the history of smallpox and of vaccination, and a description of the immunological and virological aspects of smallpox and of vaccination.

The structure of the book is defined by the chapter headings, but it may be useful to elaborate on the rationale of the nature and order of the topics covered. First, we

thought that a well-illustrated description of this now-extinct disease should be provided, so that readers would understand the nature of what was one of man's most serious diseases (Chapter 1). Then, since smallpox was caused by one virus and was eradicated through use of a vaccine which was prepared from another, related virus, there are chapters on the virology, pathology, pathogenesis and immunology of orthopoxvirus infections in general and smallpox in particular (Chapters 2 and 3). The other basic science crucial to smallpox eradication was epidemiology (Chapter 4), since eradication could not have been achieved without adequate understanding of how the disease was transmitted or if an animal reservoir had been present.

Following these four technical chapters, smallpox and its control are set in their historical perspectives in Chapters 5–8. The long and fascinating history of smallpox is summarized in Chapter 5, which deals with the history of smallpox from ancient times until the end of the 19th century, and in Chapter 8, which is concerned with its extent and incidence between 1900 and 1958, when global eradication was first proposed in the World Health Assembly. Likewise of interest is the history of the methods used to mitigate the severity of smallpox (variolation) and to prevent the disease (vaccination), which antedate other methods for successful intervention in infectious diseases. Thus Chapter 6 describes the early use of variolation and the introduction of vaccination, from the time of its discovery by Edward Jenner until the end of the 19th century. The fourth historical chapter (Chapter 7) traces developments in smallpox vaccine and vaccination up to 1958.

The succeeding 15 chapters describe various aspects of the global eradication campaign. Chapter 9 explores the development and application of the concept of eradication, the events which led to the resolution in the World Health Assembly in 1959 that global smallpox eradication be undertaken, the progress that was made in this effort between 1959 and 1966, and finally the circumstances which culminated, in 1966, in a decision to begin an intensified programme. Chapter 10 summarizes major events and developments in the Intensified Smallpox Eradication Programme throughout its course, from 1967 to 1980, and provides a perspective for subsequent chapters, which deal with operations in different parts of the world. It concludes with a series of maps of the world, graphs, and accompanying text, which encapsulate the history of this period. The provision of adequate amounts of a potent and stable vaccine and the development of better methods of vaccination were of such central importance to the Intensified Smallpox Eradication Programme that Chapter 11 is devoted in its entirety to these topics.

Chapters 12–22 describe the actual operations of the Intensified Smallpox Eradication Programme in different parts of the world on a geographical basis, corresponding, in large part, to the temporal sequence in which they were begun or strengthened. Because of travel between the endemic countries and their neighbours, as well as between them and more distant industrialized countries (from which endemic smallpox had been eliminated by 1950) there were many importations, some with serious consequences. Chapter 23 is devoted to this subject and to infections which occurred in laboratories.

The programme involved not only the eradication of smallpox, but also an array of activities designed to provide the world community with the necessary level of assurance that smallpox had indeed been eradicated. Without this, national health services would not have agreed to discontinue the vaccination of their own populations, nor would they have accepted the proposal that international travellers should be admitted without a valid vaccination certificate. Chapters 24–27 review the methods employed to certify that smallpox eradication had been accomplished, as well as observations made during the certification process.

In 1980, when the Thirty-third World Health Assembly proclaimed the achievement of global eradication, it adopted 19 recommendations made by the Global Commission for the Certification of Smallpox Eradication, for activities to

be conducted in the post-eradication era—from 1980 until the publication of this book. Chapter 28 describes the implementation of these recommendations. This is followed by a chapter detailing the investigations which were undertaken to determine the nature and public health importance of human monkeypox, the smallpox-like disease that was discovered during the eradication campaign in Africa. Chapter 30 looks again at the virology and epidemiology of smallpox, to answer—with confidence—questions about its possible recurrence or return as a human disease. The book concludes with a chapter which attempts to fulfil the request of the World Health Assembly that the book should discuss “the principles and methods that are applicable to other programmes”, and assesses the costs and benefits of the Intensified Smallpox Eradication Programme.

\*                      \*

\*

In preparing the book, the authors have availed themselves of the extensive published literature and have cited references wherever possible. For activities after 1960, they have relied most heavily on the special smallpox archives that were established in WHO Headquarters in 1980. All data in the eradication and certification chapters not ascribed to a particular source came from these archives. Personal recollections of the authors and others who have been consulted have been regularly corroborated through reference to archival material and consultation with other participants.

We have provided many detailed tables documenting matters such as disease incidence, numbers of vaccinations performed, results of assessments and costs of the programme, in recognition of the fact that few such data have been published and access to them in the WHO archives is difficult. In this sense, the book is, and is intended to be, in part archival in nature. For clarity of exposition, we have liberally supplemented these tables with maps and graphs. We have used illustrations freely, for several purposes. We have endeavoured to include a photograph, either alone or in a group, of many of the more senior persons involved in the eradication programme. We have used colour photographs to illustrate the clinical appearance and relevant virological features of smallpox and other poxvirus diseases, and colour and half-tone prints provide a flavour of the terrain and circumstances under which the campaigns were conducted in different parts of the world.

We hope that this book will enable readers to appreciate the nature and magnitude of the task of global eradication of a once-common human disease; a goal that could not have been achieved without the dedicated contributions of hundreds of international experts and tens of thousands of national health workers, working within a framework of international cooperation provided by the World Health Organization. This book bears testimony to their efforts and a remarkable adventure in public health in which we have been privileged to share.

*F. Fenner, D. A. Henderson, I. Arita, Z. Ježek*  
*Geneva, September 1987*

# Acknowledgements

In order to ensure that the contents of each chapter were as accurate as possible and provided a properly balanced view of the state of the science or the nature of the operations involved, every chapter was first read critically by all the authors. When these comments and criticisms had been evaluated and incorporated by the primary author concerned, each chapter was sent to a number of reviewers.

The reviewers were people who were judged by the authors to be knowledgeable in the field covered in a particular chapter, as a scientist, as an administrator, or as a person who had been directly involved in a particular facet of the eradication campaign. The responses of the reviewers, whose names and affiliations at the time are listed overleaf, proved most useful; the decision whether to incorporate such comments was made by the author concerned.

In addition to the reviewers, who were most generous with their time and talents, there were many others without whose efforts this book could never have become a reality. The authors wish to acknowledge several in particular. Mr John Wickett of the World Health Organization assumed responsibility for the laborious task of preparing financial analyses, reconciling morbidity data, and compiling and verifying basic data pertaining to vaccine receipts and shipments and many other items of information. He also acted as photo editor, assembling pictures from public and private sources throughout the world and preparing them for publication. To ensure uniformity of style, the diagrams and black-and-white maps were all prepared by one artist, Mr Kevin Cowan of the Australian National University. The maps in full colour were prepared by Miss Susan Hobbs in Geneva. The authors also express their gratitude to Mr Dominic Loveday and Mrs Stella Deck of the World Health Organization for their editorial work on all aspects of the book, and to Mr Loveday and Mr Keith Wynn of the World Health Organization who guided the book through to publication.

Special thanks also go to the secretaries of the WHO Smallpox Eradication unit, and notably to Mrs Susan Woolnough (secretary, 1970-1985); to Mrs Marj Lee, secretary to Dr Fenner, 1980-1987; and to Bobbie Fenner and Nana and Leigh Henderson; each of them devoted countless hours to the book.

Most of the colour and half-tone illustrations used come from the WHO Smallpox Archives; others were kindly provided by various field and laboratory workers. A few were obtained from other sources, as indicated in the acknowledgements on each plate.

Preparation of so large and complex a book as this was inevitably an expensive task. The authors are grateful to the World Health Organization for providing office facilities and access to the WHO Smallpox Archives for work done in Geneva; the two senior authors are appreciative of the financial assistance provided by the World Health Organization for clerical and technical assistance, and to the Australian National University and the Johns Hopkins University respectively for special office facilities. Finally, both the World Health Organization and the authors are grateful for the financial assistance provided specifically for the production of the book by the Finnish International Development Agency, the International Division, Ministry of Health and Welfare, Japan, and the Japan Shipbuilding Industry Foundation.

## INTRODUCTION

As this book went to press, endemic smallpox had been eradicated from Europe and North America for almost half a century and from the populous countries of China and India for some 25 and 10 years respectively. The majority of people—including the majority of physicians—now living have never seen a case of this once-dreaded disease. What was it like? For the physician, what were its clinical features and its complications? What factors influenced the prognosis? What diseases entered into its differential diagnosis? Nowhere is there a better answer to these questions than in the book written by Ricketts and illustrated by Byles over three-quarters of a century ago (Ricketts, 1908).

Since then, however, long series of carefully studied cases of both variola major (Rao, 1972) and variola minor (Marsden, 1936) have been documented, and laboratory investigation has become a powerful tool for

confirmation of the diagnosis in puzzling cases. Further, during the global smallpox eradication programme a large number of WHO epidemiologists and their national counterparts had extensive experience of smallpox as it occurred in the field in urban and rural areas and among nomads, as distinct from the hospitals from which Ricketts's, Rao's and Marsden's material was drawn. However, only limited clinical studies were possible in rural situations, outside of hospitals. The most comprehensive clinical study of variola major in a non-hospital setting is a series of 539 cases seen in their houses in Pakistani Punjab in 1966–1967 (Mack et al., 1970). Where relevant, data from this study will be used to supplement the description of hospital-based cases described by Rao (1972). An attempt has been made to interpret the symptoms in the light of current understanding of the pathogenesis and immunology of orthopoxvirus infections, as outlined in Chapter 3.

The plan of the present chapter follows Ricketts in that the account of the clinical features of smallpox consists mainly of a description of the rash, based on photographs of patients, most of which were prepared during the global smallpox eradication programme. Because smallpox is now extinct, we have to take the unusual step, in the clinical description of a human disease, of referring to it in the past tense; this was previously the case only with diseases that apparently disappeared and could be identified only by contemporary descriptions, such as the "English sweat", or the "sweating sickness".

JOYCE GREEN HOSPITAL, DARTFORD, ENGLAND

**Plate 1.1.** Thomas Frank Ricketts (1865-1918). Medical Superintendent of the Smallpox Hospitals and of the River Ambulance Service of the Metropolitan Asylums Board, London. His book on the clinical features of smallpox was based on the personal examination of many thousands of cases of variola major.

## VARIETIES OF SMALLPOX

From the time it was first recognized as a distinct disease until about the end of the 19th century, smallpox was regarded as a uniformly severe disease, associated with a high case-fatality rate, in every part of the world. Mild cases and even mild outbreaks of smallpox

were occasionally mentioned in the old literature, but they were the exception; nowhere did endemic mild smallpox occur. Smallpox was designated by many names in various languages, but no one saw a need to distinguish different varieties of smallpox, although the existence of different clinical types (see below) was recognized from the time of Thomas Sydenham (1624-1689) in Europe and much earlier in India and China.

The situation changed when Korté (1904) described a very mild smallpox-like disease, with a case-fatality rate of 1% or less in unvaccinated persons, that had occurred in South Africa for several years and was known locally as kaffir-pox, or "amaas", a word of uncertain origin, possibly a corruption of the Dutch word *masels* or *mazelen* (measles) (Dixon, 1962). Subsequently, Chapin (1913, 1926) recognized that a similar mild disease had been occurring in North America since about 1896, and had subsequently been exported from there to South America, Europe and Australia. There was controversy about the relationship of this disease to smallpox until the mid-1950s (Jong, 1956), but virological studies (see Chapter 2) showed that there was no doubt that "amaas" and "alastrim" (from the Portuguese *alastra*, something which "burns like tinder, scatters, spreads from place to place"), as it was called in South America, were indeed mild varieties of smallpox. Although many other names were used, this clinico-epidemiological variety of smallpox has come to be called "variola minor", a designation that led to the use of the term "variola major" for "classical" smallpox.

Recent studies of viral strains recovered from outbreaks of variola minor in various countries have shown that they fall into two groups distinguishable by biological properties, one consisting of strains derived from outbreaks in South America or traceable to an American source (which we shall call "alastrim" virus) and the other comprising most strains from Africa (see Chapter 2).

During the first half of the 20th century all outbreaks of smallpox in Asia and most of those in Africa were due to variola major (with case-fatality rates of 20% or more in the unvaccinated). Variola minor (with case-fatality rates of 1% or less) was endemic in some countries of Europe and of North and South America and, together with variola major, in many parts of Africa. With the more careful study that began after global eradication had been proclaimed as a goal of WHO in

1959, it was recognized that some outbreaks of smallpox in western, central and eastern Africa and in Indonesia were associated with a lower case-fatality rate than classical variola major, in the range of 5–15% instead of over 20%. Some of these lower figures resulted from aggregating all reported cases in places where both varieties of smallpox were endemic (see Chapter 8), but there were other places where this was not the explanation. The clinical picture of smallpox with a case-fatality rate of 5–15% was indistinguishable from that of variola major, both haemorrhagic and flat types of the disease occurring with about the same frequency as in classical smallpox. Preliminary tests suggested that certain laboratory characteristics of some of the strains recovered from these outbreaks were intermediate between those of variola major and variola minor (see Chapter 4), but later studies failed to support the differentiation of a separate "intermedius" virus. In this book all outbreaks of smallpox will be categorized as either variola major, with case-fatality rates of 5–25% and occasionally more, or variola minor, with case-fatality rates of about 1% or less.

### THE CLASSIFICATION OF CLINICAL TYPES OF VARIOLA MAJOR

It has long been recognized that several clinical types of variola major could be distinguished which differed in prognosis, differential diagnosis and transmissibility. The old subdivision according to the density of the focal eruption was shown by Dixon (1962) and Rao (1967) to have less prognostic value than a classification based on the nature and evolution of the rash. For this reason a WHO Scientific Group on Smallpox Eradication (1968) adopted the classification proposed by Rao and fully described in his book on smallpox (Rao, 1972). A WHO Expert Committee on Smallpox Eradication (1972) reaffirmed its acceptance of this classification (Table 1.1), according to which the commonest clinical type (ordinary-type smallpox) is subdivided in relation to the density of the rash, since this had prognostic significance. The great majority of cases of variola major seen in hospitals among both unvaccinated and vaccinated persons—88.8% and 70% respectively in Rao's series of 6942 cases

WHO, 1971

**Plate 1.2.** A. Ramachandra Rao (b. 1917). Formerly Superintendent of the Infectious Diseases Hospital, Madras, India. His book on smallpox was based on the personal study of nearly 7000 hospitalized cases of variola major. He also made important contributions to the understanding of the epidemiology of smallpox in India (see Chapter 15).

**Table 1.1.** A classification of clinical types of variola major<sup>a</sup>

Ordinary type	Raised pustular skin lesions. Three subtypes: confluent—confluent rash on face and forearms; semiconfluent—confluent rash on face, discrete elsewhere; discrete—areas of normal skin between pustules, even on face.
Modified type	Like ordinary type but with an accelerated course.
Variola sine eruptione	Fever without rash caused by variola virus; serological confirmation required.
Flat type	Pustules remained flat; usually confluent or semiconfluent. Usually fatal.
Haemorrhagic type	Widespread haemorrhages in skin and mucous membranes. Two subtypes: early, with purpuric rash; always fatal; late, with haemorrhages into base of pustules; usually fatal.

<sup>a</sup> Based on Rao (1972).

Table 1.2. The frequency and case-fatality rates of different clinical types of variola major, according to vaccination status (presence of a scar) in hospitalized patients in Madras<sup>a</sup>

Clinical type	Unvaccinated subjects			Vaccinated subjects		
	Number of cases	Percentage of total	Case-fatality rate (%)	Number of cases	Percentage of total	Case-fatality rate (%)
Ordinary type:	3 147	88.8	30.2	2 377	70.0	3.2
Confluent	808	22.8	62.0	156	4.6	26.3
Semiconfluent	847	23.9	37.0	237	7.0	8.4
Discrete	1 492	42.1	9.3	1 984	58.4	0.7
Modified type	76	2.1	0	861	25.3	0
Flat type	236	6.7	96.5	45	1.3	66.7
Haemorrhagic type:	85	2.4	96.4	115	3.4	93.9
Early	25	0.7	100.0	47	1.4	100.0
Late	60	1.7	96.8	68	2.0	89.8
Total	3 544	—	35.5	3 398	—	6.3

<sup>a</sup> Based on Rao (1972).

(Table 1.2)—were ordinary-type smallpox (and other reported series confirm this); the case-fatality rates in unvaccinated cases with confluent, semiconfluent and discrete rashes were 62%, 37% and 9.3% respectively. Although its use was suggested by Rao, such a subclassification is hardly justified for modified-type or flat-type cases, but it is useful to consider early and late haemorrhagic-type cases separately, since they were probably the results of different pathophysiological processes.

A special comment is required on the designation of cases as vaccinated by both Rao (1972) and other investigators. Until freeze-dried vaccine became available and regular assessment was made of the results of vaccination, many vaccinations, especially in tropical countries, were performed with vaccine of less than the required potency (see Chapter 11). The categorization of a subject as "vaccinated" was made on the basis of the presence of what was regarded as a vaccination scar. The presence of such a scar was, however, not certain evidence of successful vaccination. The rotary lancet, used for vaccination on the Indian subcontinent, was attended by considerable trauma, and sometimes bacterial infection alone could produce scarring. On the other hand, vaccination by the jet injector sometimes resulted in a very small scar which might be overlooked on the skin of subjects bearing many scars of traumatic origin. In spite of these shortcomings, the vaccination scar provided a more easily determined and reliable index of an individual's immune status *vis-à-vis* smallpox than was possible with other infectious diseases.

## ORDINARY-TYPE SMALLPOX

### The Incubation Period

The incubation period is the interval between the implantation of infectious virus and the onset of the first symptoms, which in smallpox were fever and constitutional disturbances. Determination of the length of the incubation period is discussed in detail in Chapter 4; in exceptional instances the duration, from the time of infection until the onset of fever, was as short as 7 days or as long as 19 days, but in the great majority of cases the period extended over 10–14 days, usually 12 days.

### Symptoms of the Pre-eruptive Stage

The incubation period in smallpox was a period of intense activity in terms of viral replication and spread within the body and the development of the immune response (see Chapter 3), of which there was at that time no clinical evidence. It ended when the patient became feverish and ill (Fig. 1.1). The onset of fever and malaise was sudden, the temperature usually rising to between 38.5 °C and 40.5 °C. Other symptoms varied in frequency (Table 1.3). Patients suffering from variola major usually complained of a splitting headache, sometimes frontal but usually generalized, and many complained of severe backache (Rao, 1972). A small proportion of children had convulsions and some adults were delirious at this stage. Vomiting occurred in about half of all patients, and

**A****B**

**Plate 1.3. A and B:** Prodromal rashes. These were best seen in fair-skinned persons (for example, Caucasians and Japanese) and were more common in those previously vaccinated. **A:** Erythematous prodromal rash on the upper arm, near the sites of vaccination performed 8 days earlier but sparing the skin immediately adjacent to the vaccination lesions. **B:** Measles-like prodromal rash on the lateral side of the trunk on the 4th day of illness. **C:** The enanthem. Lesions occurred throughout the oropharynx and in the nasal cavity, as well as on the tongue. The lesions on the palate were usually smaller than those on the posterior pharyngeal wall and tonsil. (From Uchida, 1955.)

**C**

## Day 1

**Plate I.4.** This and the next 10 colour plates illustrate the evolution and subsequent healing of the skin lesions in a 9-month-old unvaccinated Pakistani child. The rash appeared 1 day after the onset of fever, and the illustrations are categorized in terms of the day of rash. Each plate shows the ventral surface of the full body, the face, and the upper arm. This plate illustrates the first day of the rash. A few small papules are visible on the face and upper arm. An enanthem would usually have been present in the oropharynx at this time, but cannot be seen in this photograph (see Plate I.3C).

**Day 2**

**Plate I.5.** Second day of rash. More papules are present, having appeared first on the face and the upper part of the extremities.

**Day 3**

**Plate I.6.** Third day of rash. Additional lesions continue to appear and some of the papules are becoming obviously vesicular.

**Day 4**

**Plate I.7.** Fourth day of rash. All lesions had usually appeared by this time. Those that appeared earliest, on the face and upper extremities, are somewhat more mature than those that appeared later on other parts of the body, but on any specific area of the body all lesions are at approximately the same stage of development. Lesions are present on the palm of the hand.

**Day 5**

**Plate 1.8.** Fifth day of rash. Almost all the papules have now become vesicular or pustular, the truly "vesicular" stage usually being very brief. Some of the lesions on the upper arm show early umbilication.

**Day 6**

**Plate I.9.** Sixth day of rash. All the vesicles have now become pustules, which feel round and hard to the touch ("shotty"), like a foreign body.

**Day 7**

**Plate I.10.** Seventh day of rash. Many of the pustules are now umbilicated and all lesions now appear to be at the same stage of development.

**Day 8**

**Plate I.11.** Eighth day of rash. This case is now clearly classified as discrete ordinary-type smallpox. In the confluent subtype of ordinary-type smallpox the lesions would have been confluent on the face and forearms (see Plate I.18); in the semiconfluent subtype they would have been confluent on the face but not on the forearms.

**Day 9**

**Plate I.12.** Ninth day of rash. The pustules have reached their maximum size and are becoming flattened.

**Day 13**

**Plate I.13.** Thirteenth day of rash. The lesions are now scabbing, but the eyelids are more swollen than at earlier times. There is no evidence of secondary bacterial infection of the skin lesions.

**Day 20**

**Plate I.14.** Twentieth day of rash. The scabs have separated except on the palms of the hands and the soles of the feet, leaving depigmented areas.

## The Eruptive Stage

Chapter 3 concludes with an integrated picture of the pathogenesis of smallpox, which was a generalized viral infection with no recognizable primary lesion but with a viraemia whose onset was manifested clinically by the pre-eruptive fever, followed a few days later by the development of a focal eruption on the mucous membranes and skin. Following the example of Ricketts (1908), our description of the clinical features of smallpox is in large part based on illustrations, using a series of colour photographs taken for WHO during the smallpox eradication programme in Pakistan. The subject was a 9-month-old unvaccinated male infant in whom the onset of fever was recorded 1 day before the rash first appeared. He suffered from the commonest form of smallpox—discrete ordinary-type—and recovered without complications. Daily photographs were taken, until recovery was complete, of the entire subject and of face, trunk, arms and legs. Only a limited selection of these can be reproduced here, but they serve to illustrate the nature, evolution and distribution of the rash of smallpox. The temporal succession will be described in terms of the day of rash.

### *Order of appearance of the focal lesions*

The lesions on the mucous membranes (the enanthem—Plate 1.3C) were the first to appear, and they were visible on the tongue and palate, as minute red spots, about 24 hours before the appearance of rash on the skin. Lesions also occurred at this time lower down in the respiratory tract, and some patients, who complained of sore throats during this stage, had an enanthem on the pharynx.

The rash usually appeared between 2 and 4 days after the onset of fever as a few small macules ("herald spots") on the face, especially on the forehead (Plate 1.4). In a few cases the rash was first seen on the forearms or some other part of the body. Lesions then appeared on the proximal portions of the extremities, on the trunk, and lastly on the distal portions of the extremities. However, the lesions appeared in such quick succession that it was difficult to follow the timing of their occurrence on the different parts of the body, and only rarely did a patient notice this order of appearance and give such a history. Usually the rash had appeared on all parts of the body within 24 hours. Additional lesions often

appeared during the next one or two days (compare Plates 1.4, 1.5 and 1.6) but normally no fresh lesions appeared after that (Plate 1.7).

In a particular area of the body surface all the lesions were at about the same stage of evolution, although of different sizes, because the rash developed essentially as a single "crop". However, up to the 3rd day, because of the order of their appearance, there were sometimes papules on the face and macules on the legs and similarly, after scabbing had started, lesions might be scabbing on the face and still be pustular on the legs. By the 11th day many of the scabs had come off the face, the temperature had fallen and the patient felt much better. Separation of the scabs proceeded in the same order as the macules and vesicles had appeared, from the face and scalp to the trunk, arms, hands, legs and feet. By the 17th day, only the lesions in the thick-skinned palms of the hands and soles of the feet remained (Plate 1.16).

### *Evolution and distribution of the enanthem*

The enanthem evolved rapidly, because of the absence of a horny layer in the stratified epithelium of the pharynx. The minute macules became papular and vesicular and then broke down before the 3rd day (Plate 1.3C), liberating large quantities of virus into the saliva. By the 10th day they had almost healed.

The visible parts of the oropharynx most likely to show lesions were the hard palate, the tip and edges of the tongue and the pillars of the fauces. Different patients showed remarkable variations in the extent of the enanthem; in cases of equal severity the lesions were sometimes few or absent, or the mouth and throat might have been covered by a confluent enanthem that extended to the larynx and trachea. Although not as spectacular as the rash, the pharyngeal lesions were of great importance epidemiologically, as they constituted the major source from which virus was transmitted to other persons (see Chapter 4).

### *Evolution of the skin lesions*

By the 2nd day of rash the macules were raised and usually described as "papules". Reference to the histopathology indicates that this term was really a misnomer; they were raised above the skin surface because of the effusion of fluid into the tissue spaces and were in fact early vesicles (Plates 1.5 and 1.6).

G. BRAS

**Plate 1.15.** Section of a skin lesion on the 6th day of rash. Ballooning degeneration of the cells of the lower part of the epidermis has produced a loculated vesicle which is becoming pustular. The keratohyalin and horny layers form the roof of the vesicle; at the base the dermis is undamaged—there will be no scarring after healing. The central depression associated with the hair follicle on the extreme right would produce loculation of the lesion. (Haematoxylin and eosin,  $\times 50$ .)

By the 4th or 5th day they were obviously vesicular, containing at first an opalescent fluid, which became opaque and turbid in another 24–48 hours (Plates 1.7–1.9).

By the 7th day all the skin lesions were pustules (Plate 1.10) and between then and the 10th day they matured and reached their maximum size (Plates 1.11 and 1.12). By about the 11th day resolution started and the lesions flattened (Plate 1.13). The fluid was slowly absorbed, and by the end of the 2nd week the central portion hardened and finally a scab or crust formed, which later separated, leaving a depigmented area (Plate 1.14).

The palms of the hands and the soles of the feet, because of the very thick stratum corneum, were characterized by the persistence of lesions long after these had scabbed elsewhere. On the soles of the feet especially they had a very characteristic appearance (Plate 1.16). The thick cuticle lay over them and they did not protrude from its level surface, through which the disc-like scabs could be clearly seen. These lesions were called “seeds” and were often artificially removed with a

needle in attempts to hasten discharge from the hospital, where patients were usually held until the last scab had separated.

The evolution of the rash can best be appreciated by scanning the series of colour plates provided, which show the lesions daily from the 1st until the 9th day (Plates 1.4–1.12), and then on the 13th (Plate 1.13) and 20th days (Plate 1.14).

#### *Characteristics of the individual lesions*

Variolous skin lesions, which usually had only a barely perceptible erythematous areola around them, were traditionally held to have three distinctive characteristics: loculation of the cavity of the vesicle, its umbilication, and the solidity and hardness of the lesion.

*Loculation.* The reasons for loculation are clear from a consideration of the histopathology (Plate 1.15); it used to be determined in cases of smallpox by piercing the vesicle and observing that the fluid contents could not be completely emptied through the wound. However, this was a rather inefficient clinical

### Histopathology of Skin Lesions

In order properly to appreciate the clinical features of the skin lesions it is necessary to consider their histopathology. This is described in detail in Chapter 3, but it is convenient to summarize the main features of the lesions here. Plate 1.15 represents a section of part of a skin lesion in which vesiculation was beginning. The lesion occupied the whole depth of the epidermis, the deeper layers of which provided the floor and the cuticle (stratum spinosum, keratohyalin layer and horny layer) the roof. At the centre the floor was thin and as the lesion grew the deeper layer of basal cells lysed and the dermis then formed the base of the vesicle. But ordinarily (except in the face, where the numerous sebaceous glands complicated the picture) the lesion was contained within the epidermis. As infected cells became necrotic and fluid accumulated, the tissue split, the columns of epidermal cells being forced apart irregularly, so that the fissures were usually perpendicular to the surface and the vesicle consisted of several separate compartments or locules. As cellular necrosis and polymorphonuclear cell infiltration proceeded the fluid became turbid and the lesions pustular, but their turbidity was due to the extensive tissue destruction by the virus and a leukocytic reaction to this; the pus was not associated with bacterial infection.

test, in that it was readily demonstrable in cases in which there was little doubt about the diagnosis but equivocal in cases in which doubt might arise because the vesicles were small or soft. It was rarely used for differential diagnosis by workers engaged in the global smallpox eradication campaign.

*The "feel" of the lesion.* The skin lesions of smallpox were usually described as "shotty". Although as papules they projected little above the surface, they could be rolled between the thumb and forefinger and felt like hard round foreign bodies embedded in the epidermis.

*Umbilication.* This term refers to the central depression, of varying size, that was often seen in the distended vesicle. It is well illustrated in Plate 1.8. Umbilication often persisted into the pustular stage, but as the lesion progressed the fibrinous threads within it were destroyed and its surface usually became flattened because of absorption of fluid (Plates 1.11 and 1.12).

#### *Distribution of the rash*

The rash of smallpox had a characteristic "centrifugal" distribution pattern. This is apparent in the series of full-body photographs of the Pakistani infant (e.g., Plate 1.11), but is better shown in Plate 1.17. The rash was most dense on the face; more dense on the extremities than on the trunk; and, on the extremities, it was more dense on the

distal parts than on the proximal, on the extensor than on the flexor surfaces and on the convexities than on the concavities. The apex of the axilla was relatively free of lesions compared with the folds; this was known as Ricketts' sign. The palms of the hands and the soles of the feet were involved in a majority of cases (Plate 1.16).

On the face, the rash was more profuse on the upper than on the lower half, but in a small proportion of cases it was more uniformly distributed. On the trunk, it was usually denser on the back than on the front, and, on the front, it was more dense on the chest than on the abdomen. On the abdomen, the upper half usually exhibited a more profuse rash than the lower half.

Ricketts (1908) described at length the fine details of the distribution of the rash, which he regarded as a feature of great value in differential diagnosis. Such minute consideration was no longer necessary when laboratory confirmation of a tentative diagnosis became possible. Ricketts also provides several illustrations of the way in which irritation or friction could produce a local concentration of skin lesions. His suggestion that the "centrifugal" distribution of the rash was due to exposure of the face and forearms in habitually clothed persons was not supported by the universal observation of the same characteristic distribution in habitually scantily clothed patients made by workers in several countries during the global smallpox eradication programme.

### Clinical Course

The appearance and evolution of the rash in ordinary-type smallpox have already been described and illustrated. In such cases, the fever, which had fallen somewhat on the 2nd or 3rd day after the onset of the disease, when the rash first appeared, usually rose again by the 7th or 8th day and continued to remain high throughout the vesicular and pustular stages, until scabs had formed over all the lesions (see Fig. 1.1).

If secondary pyogenic infection of the skin occurred, the fever usually remained elevated. Respiratory complications, which sometimes developed on about the 8th day of the disease, were either viral or bacterial in origin. In fatal cases, death occurred between the 10th and 16th days of the illness. Among survivors, scabs separated by the 22nd–27th days, but “seeds” in the palms and soles remained much longer unless artificially removed.

### Grades of Severity

As has been pointed out earlier, so many cases of variola major belonged to the ordinary type, covering a wide range of severity, that some subdivision that was related to prognosis was found useful. That commonly employed related to the extent of the rash, and the terms “confluent”, “semiconfluent” and “discrete” were used by Rao (1972) and others. However, it is important to point out that such grades were part of a continuous spectrum; the numbers of pustules in individual cases could vary from a few to several thousand.

#### *Confluent ordinary-type smallpox*

This subtype encompassed cases in which the pustular skin lesions on the extensor surfaces of the extremities as well as those on the face were confluent (Plate 1.18). In such cases the temperature, which had fallen on the 4th or 5th day after the onset, rose again 2 days later and remained elevated until scabbing was complete. Sometimes the toxæmia did not abate and the temperature did not fall even after scabs had formed over all lesions; when this occurred the prognosis was poor. In Rao's series the case-fatality rate of confluent ordinary-type smallpox in unvaccinated subjects was 62%.

#### *Semiconfluent ordinary-type smallpox*

This was distinguished from confluent ordinary-type smallpox by an arbitrary criterion: the rash was confluent on the face but discrete on the body, including the forearms. A secondary fever often developed during the pustular stage, but the temperature and toxæmia were less marked than in the confluent subtype and the temperature subsided as soon as the scabbing had started. In Rao's series the case-fatality rate in unvaccinated subjects was 37%.

#### *Discrete ordinary-type smallpox*

This was the commonest clinical type in variola major (42% of cases in unvaccinated subjects and 58% of those in vaccinated subjects in Rao's series). Plates 1.11 and 1.17 illustrate such cases. The lesions were fewer in number and discrete (i.e., separated by normal skin) on the face and elsewhere. In some cases, although the lesions were less numerous, the course of the disease was the same as in the other two subtypes; sometimes there was no secondary fever during the pustular stage. The overall case-fatality rate was much lower than in confluent or semiconfluent ordinary-type smallpox—about 9% in unvaccinated subjects in Rao's series.

### MODIFIED-TYPE SMALLPOX

In 1908 Ricketts wrote:

“By the use of the terms ‘modified smallpox’ and ‘abortive lesions’, no assumption is made as to the state of the patient with regard to vaccination. All that is implied is that he exhibits lesions which, in certain particulars, differ from the type most common among unvaccinated patients. The papules, instead of developing into the large vesicles and pustules of natural smallpox, are transformed into lesions which are generally smaller and often of a different conformation, which do not form pustules of the usual size or wholly fail to suppurate, and which hasten through their course of evolution more quickly than is natural.”

This was written before variola minor became endemic in Great Britain. In reviewing data on 13686 cases of variola minor, Marsden (1936) suggested that:

“... the end results of the action of any of the factors which produce modification are indistinguishable in the individual patient... for example, ‘variola major’ in a vaccinated subject, or in a

**Plate I.16.** **A:** Lesions on the sole of the foot on the 14th day of rash. **B and C:** Palm of the hand and sole of the foot of a 2-year-old Zairean boy on the 21st day of rash. Elsewhere on the body the scabs had separated; on the palms and soles they remained as dark disc-like scabs ("seeds").

WHO

**Plate 1.17.** Distribution of the rash in smallpox. Dorsal and ventral views of a 3-year-old unvaccinated girl from Zaire, on the 5th day of rash. The case would be classified as mild discrete ordinary-type smallpox. The pustules were characteristically most numerous on the face, arms and legs and rather sparse on the trunk.

**Plate I.18.** Confluent ordinary-type smallpox in an unvaccinated woman in her twenties, on the 9th day of the illness. Pustules were confluent on the face, forearms and legs but discrete on the trunk. (From Stojkovic et al., 1974.)

**Plate I.19.** Modified-type smallpox. **A:** Vaccinated Japanese man aged 42 years, on the 10th day of the illness. Note the varying size of the lesions and their rapid evolution. **B:** Vaccinated Japanese woman aged 19 years. Very mild case. **C:** Adult female, Delhi, India. Note lack of toxaemia and diversity in size of lesions. (**A** and **B** from Uchida, 1955; **C** from Herrlich et al., 1967.)

### Impressions of Smallpox in Bombay in 1958

"The majority of patients had fully developed smallpox in the suppurative stage, with confluent pustules covering the entire body. The head was usually covered by what appeared to be a single pustule; the nose and the lips were glued together. When the tightly filled vesicles burst, the pus soaked through the bedsheet, became smeared on the blanket and formed thick, yellowish scabs and crusts on the skin. When the pulse was taken tags of skin remained stuck to the fingers... When secondary haemorrhage appeared, the affected area of skin formed a single black mass.

"All the gravely ill patients were also tortured by mucosal symptoms. The tongue was more or less swollen and misshapen and hindered breathing through the mouth. The voice was hoarse and faltering. Swallowing was so painful that the patients refused all nourishment and, in spite of agonizing thirst, often also refused all fluids. We saw patients with deep invasion of the respiratory passages... Wails and groans filled the rooms. The patients were conscious to their last breath.

"Some... just lay there, dull and unresponsive. They no longer shook off the flies which sat on purulent eyelids, on the openings of mouth and nose, and in swarms on the inflamed areas of the skin. But they were still alive, and with touching gestures they lifted their hands and begged for help." (Translated from Herrlich, 1958.)

naturally immune, may be indistinguishable at the bedside, as in the laboratory, from 'variola minor'. Furthermore, it is affirmed that the sole method of determining with certainty the primary factor responsible for modification in the individual patient is continued observation of the character of the disease in other patients infected by him or from a source in common with him; and, similarly, that variola major is to be distinguished from variola minor only by epidemiological study of the course of the outbreak; for the clue is to be sought in the fact that, when the infective agent is of a persistently degraded virulence (variola minor), modification of attack is invariable, because it is independent of the patient's immunity."

Following Rao, a WHO Scientific Group on Smallpox Eradication (1968) defined modified-type smallpox in much the same way as had Ricketts:

"In this clinical type, which occurs mostly in vaccinated patients, the modification relates to the character and development of the focal eruption; crusting is complete within 10 days. The pre-eruptive illness may be severe and is not necessarily of short duration, but secondary fever during the evolution of the eruption is usually absent. The skin lesions tend to evolve more quickly, are more superficial, and may not show the uniformity characteristic of the more typical smallpox eruption. The lesions are often few in number, but even when they are numerous they show some pleomorphism and evolve rapidly."

A WHO Expert Committee on Smallpox Eradication (1972) qualified this description

by relating modified-type smallpox specifically to smallpox in vaccinated persons.

When preparing this book, we debated this aspect of the definition at some length and eventually agreed to adhere to the older convention—namely, that the term "modified type" connoted smallpox that was accelerated in its clinical course, compared with the expected evolution of ordinary-type variola major, rather than smallpox whose course was modified by vaccination. By far the commonest reason for an accelerated course in variola major was vaccination some years earlier (Plate 1.19), although Mack et al. (1970), who did not categorize any cases as modified-type smallpox, noted that in their series the rapidity of maturation was not associated with either vaccination status or lesion density. In Rao's series, 25% of the cases in vaccinated subjects were classed as modified type, but only 2% of those occurring in unvaccinated subjects were so categorized. No fatal cases occurred in modified-type smallpox. Plate 1.20 illustrates the way in which even confluent lesions could progress much more rapidly than usual. However, modified-type smallpox was usually manifested by fewer lesions as well as by an accelerated clinical course.

### VARIOLA SINE ERUPTIONE

Febrile illness sometimes occurred among vaccinated contacts of cases of smallpox, with

**Plate I.20.** Confluent modified-type smallpox in a vaccinated adult male. **A:** In the papular stage but profuse. **B:** Early vesicles were confluent and suggested a severe attack, but although the face became swollen (**C**) the lesions did not increase in size and many became prematurely pus-capped. **D:** At a stage when the confluent rash of ordinary-type smallpox would have been approaching its maturity, the lesions had become encrusted and the swelling of the features had subsided. Individual lesions were small, with fleshy deep-seated bases. (From Ricketts, 1908.)

a sudden onset, a temperature of about 39 °C, headache and sometimes backache. Within 48 hours or often less the attack had subsided and the temperature was normal. Without laboratory tests it was impossible to determine whether these symptoms had been due to infection with variola virus, but the finding of high complement-fixing antibody in such patients (see Chapter 3), or a rise in antibody

titres between the first and second bleeds, indicated that the fever had indeed been due to infection with variola virus; such cases have been called variola sine eruptione (Table 1.4).

Occasionally viral isolations have been made from oropharyngeal swabs or washings from such patients. Marennikova et al. (1963) mention one such case; virus was recovered

### Contact Fever

"Variola major was introduced into Durban from India in 1943 and spread widely in South Africa. I was personally involved with one of the patients admitted to Baragwanath Hospital. The physician-in-charge phoned to say that a patient had developed a profuse rash which he felt was probably due to a virus infection. One look at the patient convinced me that she had virulent confluent smallpox. The patient coughed in my face as I was examining her. In spite of having been revaccinated many times, indeed each time I saw a patient with smallpox and again on this occasion and each time responding with an immune reaction, I developed a high fever 12 days later, beginning with chills, muscle pain, especially in the small of the back, and headache and photophobia. My throat became sore and intensely itchy and a white membrane formed on the tonsils and pharynx, presumably an outward sign of an immune reaction taking place at the virus-blood junction. Also of interest was a marked erythematous reaction which developed at the site of the inoculation of the vaccine, presumably an immunological reaction against the antigen deposited at the site in the skin. This reaction became apparent at the time of defervescence. At the same time two vesicles, one on my ankle and one on my wrist, appeared and went through the typical stages of vesicle, pustule and scab.

"My infection seems to have been a case of 'contact fever', a condition which had been recognized as occurring in fully vaccinated individuals many years ago. One of the sisters and the physician attending this patient developed a similar illness also, in spite of revaccination immediately the diagnosis was made." (J. H. S. Gear, personal communication, 1983.)

from pharyngeal swabs obtained on the 3rd day of illness from a patient who did not get a rash. Subsequently, Shelukhina et al. (1973) reported the isolation of variola virus from the throat swab of a recently vaccinated child who had been in close contact with a case of smallpox and who was feverish when the specimen was taken, but who did not develop a rash. Verlinde & Tongeren (1952) reported positive results in 2 out of 13 contacts of cases of variola major from whom pharyngeal washings were taken. One of them was a vaccinated woman from whom virus was recovered on the 14th day after contact, at a time when she had fever and constitutional symptoms. No rash developed. The other person apparently had a subclinical infection (see below).

Sometimes conjunctivitis was the only clinical manifestation of smallpox infection. Dekking et al. (1967) recovered variola virus from the tear fluid of 7 women, all thought to have had smallpox in infancy, who had signs of conjunctivitis after nursing children who died of smallpox. In a study directed at the possibility of conjunctival infection in smallpox contacts, Kempe et al. (1969) reported that conjunctivitis but no other illness developed in 21 out of 55 close family contacts of smallpox patients. Variola virus was recovered from the conjunctival exudate of 12 of them. Four of these 12 patients on whom serological tests were carried out showed antibody rises compatible with recent smallpox.

Medical attendants who had been vaccinated and revaccinated but had not often been exposed to smallpox cases sometimes suffered from what appeared to be an allergic pneumonitis ("smallpox-handler's lung"). Fever, constitutional symptoms and signs of pneumonia developed between 9 and 18 days after exposure to cases of smallpox, and X-rays showed diffuse mottling of the lungs (Howat & Arnott, 1944; Leroux et al., 1955; Evans & Foreman, 1963). None developed a rash, and attempts to recover variola virus from throat washings were unsuccessful.

### **SUBCLINICAL INFECTION WITH VARIOLA MAJOR VIRUS**

There was no easy distinction between variola sine eruptione and subclinical infection, especially among persons living in

circumstances in which malaria was endemic and feverish illnesses, from that or other causes, were so common as to be taken for granted.

### **Evidence from Viral Isolations**

Only a few virological studies of smallpox contacts have been carried out (see above and Chapters 3 and 4). Variola virus was occasionally recovered from the throat swabs of such subjects, sometimes for several days in succession, but most of them had been vaccinated and never developed symptoms. Their infections would thus have to be classified as subclinical.

### **Evidence from Serological Studies**

Serological diagnosis of past infection with variola virus depended on the fact that certain serological tests, such as the complement-fixation test, gave positive results (with high titres) for relatively short periods while others remained positive for a prolonged period, both after vaccination and after overt smallpox (Chapter 3).

Heiner et al. (1971a) carried out a detailed study of subclinical infection in villages and individual houses in West Pakistan in 1968-1969, in which overt smallpox had occurred in 68.8% of the unvaccinated and 3.2% of the vaccinated household or compound contacts. Retrospective positive serological diagnoses probably included some cases of smallpox with very few lesions and variola sine eruptione (misdiagnosed or ignored) as well as truly subclinical infections, but the figures obtained give an indication of the frequency of unrecognized smallpox as it occurred in endemic regions.

Two groups of people were studied. "Healthy contacts" were individuals who had not contracted overt smallpox, but had been household or compound contacts of a recent case of smallpox, and had not been vaccinated within 9 months of the study. The principal control group (Group 1 of Table 1.5) consisted of similar subjects who lived in the same villages but had not been in such close contact with smallpox cases. Two subsidiary control groups were used to determine the persistence of antibodies after vaccination; members of one group (Group 2 of Table 1.5) had been vaccinated annually but not within 9 months

Table 1.5. Comparison of titres of complement-fixing and haemagglutinin-inhibiting antibodies among vaccinated close contacts of cases of variola major and vaccinated controls<sup>a</sup>

	Number of close contacts	Number of controls <sup>b</sup>		
		Group 1	Group 2	Group 3
Complement fixation:	143	62	37	40
Geometric mean	38.6	< 10	< 10	< 10
% of sera $\geq 1/40$	54.5	6.5	8.1	10.0
Haemagglutination inhibition:				
Geometric mean	10.5	< 4	4.2	5.8
% of sera $\geq 1/16$	49.0	11.3	13.5	22.5

<sup>a</sup> Based on Heiner et al. (1971a).<sup>b</sup> Group 1: village contacts; Group 2: vaccinated annually; Group 3: vaccinated 5 years or more before study.

of the study, and members of the other group (Group 3 of Table 1.5) had last been vaccinated 5 years or more before the study. The highly significant differences between the close contacts and controls revealed by these tests were supported by similar results using other serological tests (neutralization, passive haemagglutination-inhibition and immunodiffusion). The frequency distribution of positive titres among the controls was unimodal, the majority being negative or having very low titres (Fig. 1.2). The titres of the contact group had a bimodal distribution, about half being negative or very low and the other half positive. This serological evidence indicates that subclinical infection that was accompanied by enough replication of virus to stimulate the production of complement-fixing and haemagglutinin-inhibiting antibodies occurred in many of the vaccinated close contacts of cases of variola major. Rao et al. (1970) came to a similar conclusion, using a gel-precipitation test with both variola and

vaccinia antigens. There was also suggestive but inconclusive evidence that inapparent infection occurred among subjects who had recovered from smallpox years before, a result that has parallels in measles (Ueda et al., 1969).

### FLAT-TYPE SMALLPOX

Flat-type smallpox was so called because the lesions remained more or less flush with the skin at the time when raised vesicles formed in ordinary-type smallpox (Plate 1.21). This manifestation of the disease was seldom encountered (6.7% of cases in unvaccinated subjects in Rao's series), and the majority of cases (72%) occurred in children. It was very rare in successfully vaccinated subjects. The prognosis was always grave and most cases were fatal (see Table 1.2).

The pre-eruptive stage lasted 3-4 days, with the usual constitutional symptoms, which were severe and continued after the appearance of the rash. The fever remained elevated throughout and the patient had severe toxæmic symptoms.

### The Rash

The enanthem on the tongue and palate was usually extensive and sometimes confluent. Occasionally a severe enanthem occurred on the rectal mucous membrane. The characteristic feature of flat-type smallpox was the nature of the skin lesions. Unlike the regular evolution seen in ordinary-type smallpox, the focal lesions in the skin matured very slowly, and at the papulovesicular stage, about 6 days after the onset of fever, a small depression was visible. By the 7th or 8th day the lesions were flat and appeared to be buried in the skin (Plate 1.21). Most lesions had haemorrhages

Fig. 1.2. Distribution of titres of complement-fixing antibodies to variola antigens in contacts and controls, as defined in text. (Data from Heiner et al., 1971a.)

into their base, the central flattened portions appeared black or dark purple, and they were surrounded by an erythematous areola. The lesions differed from those of ordinary-type smallpox in that the vesicles contained very little fluid, they were not multilocular, and they did not show umbilication. In contrast to the "shotty" feel of the lesions in ordinary-type smallpox, they were soft and velvety to the touch. No further evolution of the lesions occurred and frank pustules were rarely seen, although occasionally a few lesions, especially on the dorsum of the feet and hands, became pustular, while elsewhere on the body they remained as flat vesicles. Because of their superficial nature, the skin over the lesions peeled off after slight trauma, sometimes leaving extensive raw areas. Often the skin lesions did not conform to the classical "centrifugal" distribution.

### Clinical Course

Throughout the course of the disease the patient was toxic and febrile. Respiratory complications, including oedema of the lung and sometimes frank pneumonia, set in by the 7th or the 8th day after the onset of fever. Rao noted that unvaccinated children sometimes developed an acute dilatation of the stomach 24-48 hours before death, which usually occurred between the 8th and the 12th day. A day or two before death, the colour of the lesions changed to an ashen grey, which, along with acute dilatation of the stomach, was a bad prognostic sign. In cases with a confluent enanthem on the tongue and palate, the mucous membrane sloughed, leaving large raw areas. Some patients passed blood and mucus in the early stages of the disease, indicating the extensive involvement of the rectal mucous membrane, and in such cases, just before death, the rectal mucous membrane was sometimes sloughed off.

Among the few who survived, scabbing usually began on about the 13th-16th day after the onset of fever and was complete by about the 21st day. The scabs were thin and superficial and separated rapidly, leaving very superficial scars. Because of the bleeding into the base of the lesions, the scabs, before they dried, were purplish in colour.

Flat-type smallpox was probably due to the infection of particularly susceptible subjects with virulent strains of variola virus; it never occurred in variola minor. The appearance of

the lesions suggested a deficient cellular immune response in these patients, but no relevant studies were ever reported.

## HAEMORRHAGIC-TYPE SMALLPOX

### General Features

Considering its comparative rarity (only 200 cases in Rao's series of 6942 hospitalized patients in Madras), a great deal has been written about haemorrhagic-type smallpox. No doubt this preoccupation was partly due to the rarity of the syndrome, its great severity and the difficult problem that it presented in differential diagnosis. This was particularly true in countries in which smallpox was no longer endemic; there were many instances in which outbreaks or their extension could be traced to an unrecognized importation of haemorrhagic-type smallpox (see, for example, Benn, 1963; Stojkovic et al., 1974).

Histopathological studies (Bras, 1952a) support the clinical distinction of two varieties of haemorrhagic-type smallpox—what Curschmann (1875) and Immermann (1895) called "purpura variolosa" and "variola pustulosa haemorrhagica." We shall follow Rao (1972) in calling them early and late haemorrhagic-type smallpox respectively. Early haemorrhagic-type smallpox was characterized by haemorrhages into the skin and/or mucous membranes early in the course of the illness. Subconjunctival haemorrhages were the most common, and bleeding from the gums, epistaxis, haematemesis, haemoptysis, haematuria, as well as vaginal bleeding in women, occurred at any time in the course of the illness.

In late haemorrhagic-type smallpox haemorrhages into the skin and mucous membranes often occurred, and usually also into the bases of the developing skin lesions. Some of these cases could equally well have been considered as cases of flat-type or confluent ordinary-type smallpox, associated with haemorrhages as a complication. However, all classifications contain an arbitrary element.

Haemorrhagic-type smallpox, of both subtypes, had two unusual epidemiological features: it occurred mostly in adults (Calcutta: Guha Mazumder et al., 1975; Madras: Rao, 1972) and in some extensive series (the Calcutta and Madras series) it was as common in vaccinated as in unvaccinated subjects (see

**Plate 1.21.** Flat-type smallpox. **A:** Adult Indian man. **B** and **C:** Unvaccinated young woman from Madras, India, on the 6th day of rash; she died 3 days later. Note severe toxaemia and extensive flat pustules in both cases. (**A** from Herrlich et al., 1967.)

**Plate I.22.** Early haemorrhagic-type smallpox. **A:** In an unvaccinated 60-year-old woman, who died on the 4th day of illness. Besides the rash illustrated she bled from many other sites, with subconjunctival haemorrhages, a bloody enanthem, epistaxis, haematuria, blood in the faeces and metrorrhagia. **B:** Subconjunctival haemorrhage. **C:** Fully developed haemorrhagic diathesis and death. (**A** from Stojkovic et al., 1974; **B** and **C** from Herrlich et al., 1967.)

**Plate I.23.** Contrast between early and late haemorrhagic-type smallpox. **A and B:** Early haemorrhagic-type smallpox in a pregnant 18-year-old woman, showing severe toxæmia, petechial exanthem and bleeding from body openings; 1 hour before death. **C:** Late haemorrhagic-type smallpox in young woman, showing bleeding in base of pustules and development of a general haemorrhagic diathesis late in the disease. (From Herrlich et al., 1967.)

**Plate I.24.** Variola minor in a 30-year-old unvaccinated Somali woman, 12 days after the onset of rash. The patient was not very sick and was ambulant throughout the disease. The lesions on the face were sparse (**A**) and evolved more rapidly than those on the arms and legs (**B** and **C**).

Table 1.2). On the other hand, Sarkar et al. (1972), in a series of 170 cases observed in Calcutta during the years 1963–1969, recorded no cases of haemorrhagic-type smallpox among 81 patients who had been vaccinated but did note 32 cases among 89 unvaccinated subjects.

### Early Haemorrhagic-Type Smallpox

With minor changes, descriptions of early and late haemorrhagic-type smallpox, and statistical data relating to them, are taken from Rao (1972). There is no point in trying to distinguish a "pre-eruptive" stage in this subtype, since death usually occurred before the focal rash had time to develop. The onset was sudden and the high fever was accompanied by severe headache and backache which often persisted until the patient died. Patients looked very sick and were restless, anxious and pale. On the 2nd day of fever the whole body was suffused with a generalized erythema, and petechiae and areas of ecchymosis appeared (Plate 1.22A and C). Subconjunctival haemorrhage was the most common (Plate 1.22B), but haemorrhages occurred from many sites (Table 1.6). On the 3rd day of the disease, the whole skin exhibited a finely textured matted surface and was velvety to the touch (Plate 1.23A and B), and 24 hours later it resembled dark-purple velvet, a feature seen most clearly in fair-skinned patients.

Patients showed signs of severe toxæmia, and became restless, breathless, and complained of heaviness and pain in the chest. Ricketts (1908) described and illustrated a characteristic expression of the face, with the

features immobile, the lines of expression obliterated, the cheeks relaxed, the lips full and parted and the eyelids drooping—an expression of profound prostration. He also spoke of a fetid odour of the breath that was common to the toxæmic state in most cases of very severe smallpox, whether they were haemorrhagic, flat or confluent ordinary in type. Death occurred rather suddenly on about the 6th day of fever, patients usually remaining conscious until the end. Clinical observation and postmortem studies (Bras, 1952a) revealed that these patients did not die of haemorrhage, but they showed evidence of heart failure and sometimes oedema of the lungs. If the patient survived a few days longer, the superficial layers of the skin became raised and fluid collected underneath, forming large blebs containing serous or sero-sanguinous fluid, which ruptured after slight trauma, leaving extensive raw areas.

As was true for haemorrhagic-type smallpox in general, the early haemorrhagic subtype was more common in adults, 88% of all cases in Rao's series being in persons over 14 years of age. Two-thirds of his cases were in women, pregnant women being especially susceptible. Of all the smallpox cases occurring in pregnant women in the Madras series, 16% were of this subtype, compared with only 0.9% among non-pregnant females and 0.8% among males in the age group 15–44 years. If a vaccinated person contracted haemorrhagic-type smallpox the outcome was not influenced by the prior vaccination; indeed, Rao (1972) states that a few cases of fatal early haemorrhagic-type smallpox occurred even among persons who had recently been successfully revaccinated.

Table 1.6. Frequency of haemorrhages (percentages of cases) in different anatomical sites in early and late haemorrhagic-type smallpox<sup>a</sup>

Site or symptom	Early haemorrhagic type (72 cases)	Late haemorrhagic type (128 cases)
Skin	85	16
Conjunctiva	65	52
Haematuria	25	29
Gums	20	29
Haemoptysis	12	30
Melaena	10	8
Epistaxis	2	3
Haematemesis	1	4
Vagina (women only)	90	58

<sup>a</sup> Based on Rao (1972).

### Late Haemorrhagic-Type Smallpox

This form was differentiated from early haemorrhagic-type smallpox by the occurrence of haemorrhages after the appearance of the rash. The pre-eruptive stage lasted for 3-4 days, the temperature being about 40 °C, with severe toxæmic symptoms like those described for early haemorrhagic-type smallpox, which continued unabated even after the appearance of the rash. The lesions, which started as macules, soon became papules but thereafter matured very slowly. They sometimes showed haemorrhages into their bases, which gave them a "flat" appearance (Plate 1.23C). Bras (1952a) noted that sections of such lesions showed that often the bleeding actually occurred in the corium beneath the pustules rather than in the pustules themselves.

Bleeding occurred in various mucous membranes, although somewhat less frequently than in early haemorrhagic-type smallpox (Table 1.6). If the haemorrhagic focal lesions were "flat", they did not evolve beyond the vesicular stage but then flattened out and became black. In about 15% of Rao's cases they matured into pustules, which followed the same course as in ordinary-type smallpox. In these cases there were no haemorrhages into the lesions, but only into mucous membranes.

The majority of cases of late haemorrhagic-type smallpox were fatal (see Table 1.2), death occurring between the 8th and the 10th day. Cases with flat lesions had a higher fatality rate than those with raised pustular lesions. Among the patients who survived, the haemorrhages gradually resolved during a prolonged convalescence. However, in the few survivors among cases with the flat type of lesions, scabs usually formed sooner, resulting in only superficial scarring.

Of cases in the Madras series, 80% occurred in persons over 14 years old. Unlike the situation with early haemorrhagic-type smallpox, there was little difference in frequency between men and women, although pregnant women were slightly more susceptible. In Rao's series, of all pregnant women with smallpox, 6% had the late haemorrhagic type, compared with 2% of non-pregnant females and 2.1% of males in the age group 15-44 years. As with early haemorrhagic-type smallpox, Rao observed cases among persons who had apparently been successfully vaccinated, not only in infancy but also at later ages.

Haemorrhagic-type smallpox was primarily due to defects in the response to infection by individual patients. It was very rare in *variola minor* (see below), but epidemiological evidence suggested that viral strains of unusual virulence were not the main cause of haemorrhagic-type smallpox. For example, Rao (1972) noted that there had not been a single haemorrhagic-type case among the contacts of 385 cases of haemorrhagic-type smallpox in Madras, although many of these contacts had contracted other forms of smallpox; this was an even longer series than that analysed in Table 1.2. Postmortem studies (Bras, 1952a) excluded concomitant bacterial infection as a precipitating factor. As will be shown in a later section, these cases were characterized by high and sustained viraemia, severe depletion of platelets and a poorly developed humoral immune response.

### VARIOLA MINOR

This variety of smallpox differed greatly from *variola major* in its spectrum of severity and in its case-fatality rates—about 1% compared with about 20%.

#### Clinical Course

The most comprehensive account of the symptomatology of this disease was provided by Marsden (1936). His observations were based on 13686 cases (most of which he examined personally) that occurred in London between 1928 and 1934. The description which follows is drawn largely from that source, supplemented by the accounts of MacCallum & Moody (1921), Jong (1956) and Noble et al. (1970), and the extensive field experience of epidemiologists working in Brazil, Ethiopia and Somalia during the smallpox eradication programmes in those countries.

Almost all cases of *variola minor* would have been classified as discrete ordinary- or modified-type smallpox, but in any individual case it was impossible to determine whether the disease was *variola major* or *variola minor*. The diagnosis depended on the assessment of the clinical severity of the outbreak; if there were no deaths or only one among 50 or so patients the disease was usually *variola minor*. Data on the pre-eruptive stage were provided by Marsden, who saw only about 1% of his cases at this stage, and MacCallum & Moody

JOYCE GREEN HOSPITAL, DARTFORD, ENGLAND

**Plate 1.25.** James Pickford Marsden (1900-1977). Formerly Deputy Medical Superintendent, River Hospitals (London County Council), Dartford, Kent, England. He described a series of 13 686 cases of variola minor in outbreaks in London between 1928 and 1934.

(1921), who saw many of the 2333 cases in their Jamaican series during the early stages of the disease. The onset was sudden, with a fever of 40 °C, severe headache and backache and sometimes vomiting. Marsden recorded the occurrence of pre-eruptive rashes in 48 of the cases he saw during this stage; there were typical erythematous prodromal rashes in 37 cases. MacCallum & Moody recorded no such rashes in their mainly dark-skinned patients. The constitutional symptoms of the established disease were usually much less severe than those in cases of variola major with a comparable rash (Plate 1.24). The toxæmia so evident in variola major rarely occurred, and patients with extensive skin rashes were often ambulant. The individual lesions were smaller than those of variola major, so that Marsden was able to count more than 500

lesions on the faces of 295 of his patients without these producing confluence, as would have been expected in variola major. Both MacCallum & Moody and Jong noted that the early vesicles and early pustules were unilocular and were not umbilicated, a clinical finding that was supported by histological examination of biopsy material. The sequence of appearance, the distribution and the nature of the skin lesions were similar to those described earlier for variola major, but their evolution was often more rapid. The eruption became vesicular on the 3rd day after the appearance of the first papules, and within 24 hours had become pustular. Early crusting was established on the 6th or 7th day of rash.

Cases of variola minor could not be classified according to Rao's scheme (see Table 1.1) because of the smaller size and more rapid evolution of the skin lesions. Indeed, the vast majority would have been classified as "modified-type smallpox", which would clearly be a misnomer. Marsden grouped his cases according to the criteria formulated by Ricketts (1893) (Table 1.7). He noted that many of those classified as "discrete" would have been confluent in variola major; none was described as flat-type smallpox.

In keeping with the reduced severity and the more rapid evolution of the rash, secondary fever was rare, occurring in most of the more severe cases but, in Marsden's experience, in only 0.13% of those with fewer than 100 lesions on the face, a group which included 87% of the cases in his series. Both MacCallum & Moody and Jong noted the absence in variola minor of the characteristic fetid odour of variola major.

Haemorrhagic-type cases did occur in variola minor, but they were extremely rare. Marsden recorded 3 cases, one of which recovered; Tigre et al. (1973) describe a fatal case in a 4-year-old boy infected in Argentina in 1970 and refer to 4 others observed in Brazil; Rodrigues-da-Silva et al. (1963) recorded 1 case which survived, and Moody (1922) recorded 2 fatal cases, both in pregnant

women, among 2912 cases of variola minor in an epidemic in Jamaica in 1920-1921.

There were 150 pregnant women in Marsden's series but he commented only on the effects on the fetus, described below, and not on the severity of disease in the mother. The mortality in the Jamaica outbreak described by MacCallum & Moody (1921) was 0.4%, but of the 5 women who died 4 were 6 or 7 months pregnant and all of them displayed a "marked tendency to haemorrhage".

### Variola Sine Eruptione and Subclinical Infection

In a susceptible population the host resistance to any infection has a Gaussian distribution. The data on variola major (see Table 1.2) suggest that there would be few cases of variola sine eruptione and subclinical infection in unvaccinated persons exposed to this infection; however, many more such cases might be expected to occur in variola minor (Table 1.7). Data on the occurrence of such infections are difficult to find, but observations made in Brazil during the 1960s support this view. Positive titres of complement-fixing antibody were found in 6 asymptomatic contacts of children with overt variola minor; most of the contacts had not been vaccinated more recently than 20 years before (Rodrigues-da-Silva et al., 1963). In a carefully studied ward outbreak, Salles-Gomes et al. (1965) observed positive complement-fixing and sometimes haemagglutinin-inhibiting antibody responses among 13 contacts exposed to overt variola minor. Four of these cases occurred in previously fully susceptible patients who had never had variola or been vaccinated.

## SMALLPOX ACQUIRED BY UNUSUAL ROUTES OF INFECTION

### Inoculation Variola and Variolation

Under unusual conditions, smallpox could be accidentally acquired through inoculation. Such cases sometimes occurred among nursing mothers and among those engaged in postmortem work (Lyons & Dixon, 1953), and cutaneous infections were recorded in an outbreak among lace-workers (Boobyer, 1894). Marsden (1936) recorded 50 cases of accidental smallpox inoculation in variola minor and noted that the lesions of inocula-

tion were usually recognized by their larger size and more advanced development than the other elements of the focal rash.

Much more common, however, was the practice of deliberately inoculating variola virus into the skin, practised since ancient times in Africa and India and in China (where, however, infection was usually produced by nasal insufflation) and on a large scale in some parts of Europe and North America during the 18th century (see Chapter 6). Variolation continued to be practised in many parts of Africa and in Afghanistan and Pakistan until quite recent times, and the spread from variolated individuals was an important source of smallpox in Afghanistan and Ethiopia up to the time of eradication in 1973 and 1976 respectively.

The technique of cutaneous variolation has varied at different times and in different places. Detailed descriptions of the methods used during the 18th century in France and other countries of Europe and in North America can be found in Miller (1957) and Razzell (1977b); methods used more recently in Africa and Asia are described in Chapters 14 and 21.

### Clinical picture

The clinical picture of inoculation smallpox was influenced by several factors. Inoculation carried out after the manner of modern vaccination produced a local skin lesion that first appeared as a small papule on the 3rd day after the operation. It grew in size and became vesicular by the 5th day, and by the 8th or 9th day there was a large pustular lesion with much surrounding erythema and oedema (see Chapter 6, Plates 6.1-6.3). Fever and constitutional symptoms corresponding to the pre-eruptive stage of ordinary-type smallpox began on the 8th day and often lasted for only 2 or 3 days (Fig. 1.3). There were usually a number of secondary lesions around the primary lesion (see Plates 6.1-6.3), and the generalized rash began on the 9th day on the face, often consisting of very scanty macules, which rapidly became vesicular. Subsequent lesions sometimes appeared over the next 3 or 4 days and evolved more rapidly than in smallpox acquired by the respiratory route. Even in the few cases that had a large number of secondary pustules (which in inoculation smallpox amounted to as many as 300-1000), the lesions matured more rapidly than in

Fig. 1.3. The clinical course of moderately severe ordinary-type variola major in an unvaccinated subject (A); inoculation smallpox (variola) in an unvaccinated subject (B); and primary vaccination (C). (Temperature records from an illustration in Hime (1896) with modified wording.)

ordinary-type smallpox, so that scabbing occurred 3 or 4 days earlier and the lesions, being more superficial, gave rise to less scarring. By the 18th or 19th day most of the scabs, except for the lesions on the palms of the hands and the soles of the feet, had been shed.

Neither haemorrhagic- nor flat-type smallpox seems to have been recorded as a sequel to variola, at least in European and North American practice. This may have been due to the professional interests of the inoculators and their concern to be exempt from any possible blame for deaths that occurred; but, in any event, it was the practice to avoid inoculating especially susceptible persons—pregnant women, children under 2 years of age and the aged and infirm.

Apart from the primary skin lesion, most cases, like those of naturally acquired inoculation smallpox, appeared to fall into the category of modified-type smallpox. Cases with only a primary skin lesion, 1 or 2 days of fever and no rash—variola sine eruptione

were said to be not uncommon. Rao himself suffered from such an infection (Rao, 1972).

Because of the smaller number of lesions and their more rapid maturation, cases of inoculation smallpox were less infectious, and were infectious for shorter periods, than those of smallpox acquired by the respiratory route. Nevertheless, they often did initiate smallpox in unvaccinated (and unvariolated) contacts, both in 18th century practice in Europe and North America and in recent times in Afghanistan and Ethiopia. Such contact cases were no different from those associated with other epidemics due to whatever strain happened to have been used for variolation.

#### Severity

In the hands of some of the famous British practitioners of variolation (e.g., the Suttons—see Razzell, 1977b) the severity of smallpox due to variolation appears to have been low and the mortality less than 2%.

In their day only variola major virus was circulating in Great Britain and some contact cases acquired severe and sometimes fatal smallpox; the explanation for the mild nature of smallpox after variolation lay with the age and health of the inoculated subjects, the route of inoculation and the small dose usually employed.

In Ethiopia, where variolation was practised until 1976, the virus used during the last few decades was variola minor and inoculation smallpox was correspondingly mild; nevertheless, it was an important source of outbreaks during the latter part of the eradication campaign in that country (see Chapter 21).

### Congenital Smallpox

The effects of pregnancy on the clinical course of smallpox in the mother are discussed later in this chapter. Infection of the fetus depended on the growth of the virus in the placenta and its subsequent release into the cord blood. Its frequency was uncertain, since most pregnant women suffering from variola major aborted during the pre-eruptive fever. Occasionally babies born of mothers suffering from smallpox developed symptoms after birth; Rao (1972) records 10 such cases among 116 live births. In these babies, all of whom died, the fever-to-fever interval was 9–12 days. Among the offspring of 84 women who suffered from haemorrhagic-type smallpox (all with intense and sustained viraemia) none of the 21 children born alive developed clinically recognizable congenital smallpox, but 17 of them died in less than 72 hours—too soon for a diagnosis to be made.

The baby was infected in half of 34 pregnancies in which the mother was infected with variola minor during late pregnancy (Marsden & Greenfield, 1934). Usually the infection was acquired *in utero*, at the time of the mother's viraemia; the incubation period then appeared to be 8–9 days, as in inoculation smallpox. If the fetus escaped infection during that time the infant might become infected at birth or later in the neonatal period, especially if the mother's rash was then at an early stage of development. If the mother carried the fetus to term, the newborn infant was usually temporarily immune from smallpox because of maternal antibodies.

Fetal variola was a rare occurrence, reported only in variola minor. In some cases

(MacCallum & Moody, 1921; Ribeiro et al., 1965) the fetus sustained an attack of smallpox *in utero* and was subsequently born alive, having been infected at the time the mother had the disease 2 or 3 months before birth. More often (for example in 8 of the 20 pregnant women in the series described by MacCallum & Moody (1921)) abortion occurred and the macerated fetus was marked with scars from an attack of variola minor sustained *in utero*.

Nowhere in the scientific literature is there a reliable reference to the occurrence of congenital defects caused by smallpox or vaccination in a pregnant woman. Since the usual viral causes of congenital defects are non-cytocidal viruses, whereas variola and vaccinia viruses are both cytocidal, this is not unexpected.

### EFFECTS OF VACCINATION ON THE CLINICAL COURSE OF SMALLPOX

The most important effect of vaccination was the protection of the subject from smallpox, but prior vaccination, even many years before, usually influenced the course of the disease in persons who did show symptoms. The situation in individual subjects depended on a variety of factors, some relating to the host: genetic resistance, physiological state, and interval since vaccination or revaccination; some to the vaccine and its mode of delivery: the strain of vaccinia virus used, the potency of the vaccine and the inoculation procedure employed; and, finally, of course, whether the infection was due to variola major or variola minor virus. Further, it was the general practice to vaccinate or revaccinate contacts; some of these individuals were incubating smallpox at the time of vaccination.

Successful vaccination within 5 years of exposure provided a high level of protection against smallpox. When vaccination had been performed more than 20 years before exposure there was sometimes no residual immunity and the course of the disease was similar to that seen in unvaccinated subjects, although even then the outcome, examined statistically, was modified (Hanna, 1913).

Although its most important effect was the prevention of infection, vaccination also influenced the frequency of different clinical types of smallpox among persons who did contract the disease (see Table 1.2). Not only

was modified-type smallpox much more common among vaccinated patients (25.3% compared with 2.1% in Rao's series), but a larger proportion of ordinary-type cases was classified as discrete (83.5% compared with 47.4%) and flat-type cases were less common (1.3% compared with 6.7%). However, Rao (1972) and Guha Mazumder et al. (1975) reported that, among those who got smallpox, haemorrhagic-type smallpox was slightly more common among vaccinated than among unvaccinated subjects (see Table 1.2 and below). Not all investigators agreed with this view; for example, Sarkar et al. (1972) reported that in a series of 170 cases no cases of haemorrhagic-type smallpox occurred among vaccinated persons, but 32 cases occurred in unvaccinated subjects. Except in modified-type smallpox, which was hardly ever fatal, and haemorrhagic-type, which was almost always fatal, the case-fatality rates were lower in vaccinated than in unvaccinated patients (see Table 1.2).

Vaccination resulted in the modification of three aspects: the toxæmia (and correspondingly the case-fatality rate), the number of lesions, and the character and evolution of the rash. The waning of vaccine protection against these manifestations did not occur uniformly.

### Effects of Vaccination on Toxæmia

The initial constitutional symptoms of smallpox were associated with the replication of variola virus during the incubation period, the end of which was marked by the sudden onset of fever and headache that accompanied the secondary viraemia. In some cases vaccine protection had little apparent effect on symptoms of fever and headache at the end of the incubation period, but no skin lesions developed; the patient was said to have suffered from *variola sine eruptione*, which was occasionally associated with pneumonitis. Sometimes the pre-eruptive stage in vaccinated subjects was accompanied by a fleeting erythematous rash that particularly affected the flexures.

The more toxic forms of smallpox, except for the haemorrhagic type, were much less common in vaccinated than in unvaccinated subjects (see Table 1.2).

### Effects of Vaccination on the Number of Lesions

The skin lesions were initiated by the infection of dermal capillaries by virus released into the circulation during the secondary viraemia (see Chapter 3). Prior vaccination usually reduced the level of viraemia and thus the opportunity for skin lesions to develop; *variola sine eruptione* occurred mainly in vaccinated persons, and confluent lesions were much less common among vaccinated subjects. In Rao's series 16.5% of vaccinated patients who had ordinary-type smallpox were classified as confluent or semi-confluent, compared with 52.6% of unvaccinated patients.

### Effects of Vaccination on the Character and Evolution of the Rash

In some cases of smallpox in vaccinated subjects the character and rate of evolution of the rash differed from the usual pattern, presumably because of the anamnestic response initiated by infection with variola virus in the vaccinated subject. The individual lesions were more superficial and hence did not have the "shotty" feel, and their edges were often irregular. Umbilication and loculation were not found in these superficial lesions, which resembled those of chickenpox. Often the modified lesions were very small, but they could vary quite considerably in size in any particular area of skin (Plate 1.19C). In fair-skinned subjects the red areola around the pustules was often more pronounced—presumably an allergic manifestation. In many vaccinated subjects the rash also evolved more rapidly so that the lesions passed through the stages of macule, vesicle and pustule in 3 or 4 days instead of 7 or 8. On the other hand, many field workers found no such differences in symptomatology, apart from a greater frequency of cases of ordinary-type smallpox with few skin lesions. Smallpox in vaccinated subjects who did contract the disease was no different in other respects from that found in unvaccinated patients. Mack et al. (1970), in cases with similar lesion density, found no differences that could be related to vaccination status in the length of the pre-eruptive stage, the rate of maturation of skin lesions, the occurrence of corneal lesions, the case-fatality rate or the prevalence of residual pockmarks.

### Effects of Vaccination in Variola Minor

In Marsden's series, variola minor occurred in 1756 patients who showed evidence of having been successfully vaccinated, out of a total of 13 686 cases. In only 2 of these was there evidence of vaccination within the previous 5 years and in only 7 within the previous 10 years; the great majority had been vaccinated 20 or more years earlier. In an epidemic in the Netherlands, Jong (1956) found no cases in persons vaccinated less than 30 years before, and, in Brazil, Suzart de Carvalho Filho et al. (1970) found a vaccine-efficacy ratio of 94%, regardless of the interval since previous vaccination (see Chapter 12). Vaccination thus provided very good protection against variola minor, a conclusion which is in keeping with the experience of epidemiologists working in Ethiopia and Somalia during the global smallpox eradication programme.

### LABORATORY FINDINGS

Laboratory observations on cases of smallpox will be described in Chapter 3, as part of an attempt to build up a coherent picture of the pathogenesis of the disease. However, it is useful to examine some of the results here in the context of the symptomatology of smallpox.

#### Virological Observations

The principal value of the laboratory, without which it would have been impossible confidently to certify global smallpox eradication, was the demonstration of the presence or absence of variola virus in vesicle fluid and crusts from suspected cases of smallpox (see below). This section reviews virological findings made on cases of smallpox which may help to explain the clinical signs and symptoms.

#### *Viraemia*

According to the model for the pathogenesis of variola developed in Chapter 3, there was an early transient viraemia soon after infection. The virus then replicated in the lymph nodes, spleen and bone marrow until just before the onset of symptoms, which was associated with secondary viraemia. All the

reported observations of viraemia in smallpox relate to this "secondary" viraemia.

Precise observations were never made on the distribution of variola virions among the various components of the blood (plasma, leukocytes and erythrocytes); by analogy with other poxvirus infections viraemia would have been expected to be primarily cell-associated (see Chapter 3). However, most observations that were made on the blood of smallpox patients utilized either serum or lysed whole blood, the material being inoculated either into monkeys (Kyrle & Morawetz, 1915) or on the chorioallantoic membrane of chick embryos (Downie et al., 1950, 1953, 1969b; Mitra et al., 1966). In haemorrhagic-type smallpox both serum and lysed blood gave positive results; it is possible that viraemia might have been detected more readily in cases of ordinary-type smallpox if separated leukocytes had been examined.

However, the general pattern appears to have been consistent. Although viraemia must always have occurred, virus was only rarely recovered from the blood or serum from cases of ordinary-type smallpox. Downie et al. (1950, 1953) and Mitra et al. (1966) recorded one or two positive results out of many attempts in such cases and then only in the early days of the disease. The picture in haemorrhagic-type smallpox was quite different. Virus was readily recovered from the blood of all cases, the titres were usually high, as determined by titration on the chorioallantoic membrane of chick embryos (Downie et al., 1953, 1969b; Mitra et al., 1966; Sarkar et al., 1969), and viraemia usually persisted until the patient died. Downie et al. (1969b) noted that viraemia was consistently much higher in cases of early than of late haemorrhagic-type smallpox. Patients with haemorrhagic-type smallpox usually also had soluble antigens in their bloodstream (antigenaemia), the level of which was roughly correlated with the level of the viraemia. Although few opportunities occurred for its practical use, the demonstration of antigen in the serum provided a useful and rapid laboratory diagnostic test for haemorrhagic-type smallpox, a disease in which the differential diagnosis was extremely difficult, especially in non-endemic countries, in which it would rarely have been suspected.

Thus haemorrhagic-type smallpox appears to have been associated with overwhelming infection and the continued release of virus from infected cells into the bloodstream; in

other cases demonstrable viraemia was usually restricted to the pre-eruptive and early eruptive stages of the disease.

### *Skin*

Variola virus could be readily demonstrated in the skin lesions of all cases of smallpox, from the earliest stages of the rash until the scabs separated. The large amount of virus in the vesicle fluid was eventually included within the scabs. However, because virus in the scabs was associated with large flakes of inspissated material it appeared to be relatively unimportant as a source of infectivity for contacts, compared with virus in the oropharyngeal secretions (see Chapter 4). In spite of the absence of vesicles or pustules, the skin of cases of haemorrhagic-type smallpox contained very large numbers of virions.

### *Oral and pharyngeal mucous membranes*

The earliest focal lesions in smallpox occurred in the oropharynx, and instead of forming papules and vesicles, as in the skin, these lesions soon ulcerated and thus liberated large amounts of virus into the saliva. This was the major source of infectious virus as far as the transmission of smallpox was concerned (see Chapter 4).

### *Conjunctiva*

Patients with smallpox sometimes had conjunctivitis. Virus could be readily recovered from the conjunctival swabs of patients in whom conjunctivitis developed early in the course of the disease, but usually not from convalescent patients who developed conjunctivitis (Dekking et al., 1967; Kempe et al., 1969; Sarkar et al., 1973a). The occasional appearance of variolous conjunctivitis at or before the onset of fever suggested to Kempe et al. (1969) that the conjunctiva may have been the portal of entry in these cases.

### *Urine*

The interpretation of the results of testing urine for virus was difficult, since patients often had pustules on the skin near the urethral orifice, and catheterization, had it been possible to do this aseptically, was not ethically justifiable. However, viruria was recorded by all investigators who tested the urine from cases of variola major. Positive

results were recorded by Downie et al. (1965a) in 17 out of 34 specimens, and by Sarkar et al. (1973a) in 21 out of 39. The viruria was greater in degree and more persistent in severe cases (haemorrhagic-type smallpox and those with a confluent rash) than in milder cases. No virus was detected in the urine of some cases whose severity was comparable to that of cases with viruria.

## Serological Observations

The immune response in generalized orthopoxvirus infections (including smallpox) is described in Chapter 3; this section summarizes information on the correlation between various serological responses and the clinical severity of smallpox, to the extent that such information is available. Unfortunately, there is an almost complete lack of data on cell-mediated immunity in smallpox, an immune response that was probably of critical importance in the pathogenesis and immunopathology of the disease.

The most comprehensive studies on the serological responses in cases of smallpox are those reported by Downie et al. (1969a,b) on ordinary-type and haemorrhagic-type smallpox, using haemagglutination-inhibition, complement-fixation, gel-precipitation and neutralization tests. In most cases of non-fatal ordinary-type smallpox, antibody was detected by haemagglutination-inhibition and neutralization tests between the 6th and 8th days after the onset; by complement fixation and gel precipitation about 2 days later (Fig. 1.4). The antibody response was slower and

Fig. 1.4. Percentages of positive antibody titres obtained at various times after the onset of ordinary-type variola major, by 4 types of serological test, in 151 subjects of whom 127 had been vaccinated, usually many years before. (From Downie et al., 1969a.)

the titres were lower in early haemorrhagic-type smallpox than in other cases (Sarkar et al., 1967, 1969), but Downie et al. (1969b) found haemagglutinin-inhibiting antibodies in most cases of haemorrhagic-type smallpox, although both neutralizing and complement-fixing antibodies were at much lower levels or absent in such cases.

As might be expected, antibodies usually appeared earlier and reached higher levels in vaccinated than in unvaccinated patients (Downie & McCarthy, 1958).

### Haematological Observations

The blood picture in smallpox varied according to the nature of the case and the stage of the disease. In most cases there was little change in the red blood cell count, but during the eruptive stage the numbers of granular leukocytes usually fell and a relative and absolute increase in the numbers of lymphocytes occurred. The granulocytopenia was often reversed during the late pustular stage, perhaps because of secondary infection of the skin lesions in some cases.

In early haemorrhagic-type smallpox there was often a striking change in the blood picture, which Ikeda (1925) considered to be of diagnostic value. Pathological forms of normoblasts with basophil stippling or polychromatophilia were common; the total

leukocyte count was increased by 30–40%, with a marked augmentation in the numbers of lymphocytes and monocytes; and the presence of myelocytes and myeloblasts suggested an intense stimulation of the bone marrow. In contrast to the rise in the number of platelets found after the vesicular stage in many other cases of smallpox, Ikeda discovered that there was a marked and progressive thrombocytopenia in haemorrhagic-type smallpox, the number of circulating platelets often falling to a very low level.

Sarkar et al. (1968) compared the concentrations of various serum proteins in 28 sera from cases of smallpox of different clinical severity with those of an equal number of normal subjects. The total proteins were unchanged, but albumin was diminished and globulin increased, the increase being associated with fractions  $\alpha_2$  and  $\gamma$ . There was no correlation between the concentrations of any of these proteins and the level of haemagglutinin-inhibiting antibodies.

More detailed studies of the pathophysiology of bleeding were carried out on patients in Madras and reported by McKenzie et al. (1965) and Roberts et al. (1965). Their findings in relation to vascular integrity, platelet function and blood coagulation are summarized in Table 1.8, which illustrates the generality of impaired functions in haemorrhagic smallpox, especially evident in the early type. In contrast to Ikeda (1925), these

Table 1.8. Results of tests for platelet function, vascular integrity and blood coagulation in smallpox<sup>a</sup>

Test	Ordinary-type smallpox (8 patients)	Haemorrhagic-type smallpox (35 patients)	
		Early	Late

Platelet count per mm <sup>3</sup> (range) (normal: 275 000 ± 100 000)	< 20 000 to 303 000	< 20 000 to 128 000	< 20 000 to 138 000

<sup>a</sup> Based on McKenzie et al. (1965).

investigators found that many patients with smallpox but with no clinical evidence of haemorrhage had moderate to severe thrombocytopenia but usually no other coagulation defect. Patients with late haemorrhagic-type smallpox had severe thrombocytopenia and some had a mild to moderate decrease in prothrombin and a moderate decrease in accelerator globulin. As expected, the cases of early haemorrhagic-type smallpox were characterized by multiple defects, with significant and specific coagulation defects in addition to severe thrombocytopenia. All had an elevated thrombin time and a total absence of accelerator globulin, which the authors ascribed to disseminated intravascular coagulation. At autopsy such cases showed disseminated intravascular thrombosis involving small vessels in many organs.

## COMPLICATIONS

Complications of two kinds occurred in smallpox. One group was due either directly or indirectly to viral activity in an unusual site, the other to secondary bacterial infection.

### The Skin

As noted earlier, pustulation was part of the natural sequence of development of the skin lesions in smallpox. However, in most countries in the days before antibiotics were available and, even recently, in those in which hygiene was poor and such treatment not obtainable, secondary bacterial infection of the skin lesions often occurred, sometimes to an extent that Ricketts (1908) described as "thousands of boils". In pre-antibiotic days septic complications also occurred in variola minor; Marsden (1936) recorded the presence of boils in 3.65% and of septic dermatitis in 2.3% of his series of cases. Even higher percentages of these complications were seen in the Ogaden desert during the late stages of the eradication programme in Somalia (Ježek et al., 1981).

### Ocular System

Mild conjunctivitis, occurring early in the course of the disease, or at the time of the eruption if there were lesions on the eyelids, was essentially part of the acute disease and not a complication. Sometimes it was the only

symptom (Dekking et al., 1967). Pocks often occurred on the margins of the eyelids but not on the avascular cornea. Often there was much swelling of the eyelids (see Plate 1.13), which made it difficult to open the eyes. Dixon (1962) suggests that it was this swelling, rather than keratitis or corneal ulceration, that accounted for the frequent references in the old non-technical literature that a person was "blind with smallpox". Corneal ulceration and sometimes keratitis did occur in smallpox. These complications were common in haemorrhagic-type smallpox, but were of relatively minor importance because such patients soon died. In ordinary-type smallpox corneal ulceration occurred at about the end of the 2nd week of illness, beginning at the corneal margin. Sometimes the ulcers healed rapidly and there was only a trivial opacity; on other occasions there was severe corneal scarring. Both Dixon (1962) and Rao (1972) note that keratitis and corneal ulceration were far more common in malnourished children than in the well nourished; for this reason these conditions continued to be more important complications in developing countries than in the more prosperous industrialized countries. Mack et al. (1970) reported that 28 out of 405 patients examined within 6 weeks of onset in a rural setting in Pakistani Punjab had corneal lesions, which occurred mostly in patients with confluent or semiconfluent rashes. Three out of 11 patients seen a year later had permanent ocular lesions, and 4 other instances of permanent lesions were observed in 148 cases in whom lesions had not originally been seen. The overall rate of residual corneal opacity in those surviving smallpox was 4.4%. Corneal ulcers occurred in 1% of cases in Rao's series (excluding haemorrhagic-type smallpox) and keratitis in about 0.25%.

### Joints and Bones

Arthritis, associated with involvement of the bones of the joints, was a relatively common complication of smallpox, occurring in 1.7% of cases in Rao's series, usually in children. Cockshott & MacGregor (1958) and Cockshott (1965) reviewed the condition, which they called "osteomyelitis variolosa", and described a series of cases observed in Nigeria. More recently, Gupta & Srivasta (1973) reviewed the X-ray features of 20 cases observed in India. The elbow was the most commonly affected joint and symmetrical

**Plate 1.26.** Osteomyelitis variolosa in an unvaccinated Nigerian child. Joint symptoms appeared 1 week after the onset of rash and affected both elbows. **A:** External appearance, showing hypopigmented spots of healed exanthem and swollen elbows. **B:** X-ray appearances (From Cockshott & MacGregor, 1958.)

bilateral joint involvement was frequent (Plate 1.26). Although secondary bacterial infection sometimes occurred, the disease was primarily due to viral infection of the metaphyses of growing bones. The primary bone lesion was probably a proliferating arteritis, which led to fibrosis, necrosis and bone resorption (Eeckels et al, 1964).

This complication usually occurred late in the course of the disease, after the 15th day, and was accompanied by a brief recurrence of

fever during the scabbing stage. Because of the severity of smallpox itself, and the insidious nature of the bone and joint involvement, cases were often missed during the attack, and only recognized as probably having been due to smallpox years afterwards because of a variety of bone defects for which there were no other explanations (Gupta & Srivasta, 1973).

### Respiratory System

Rao (1972) regarded respiratory complications as common in severe smallpox, especially in the unvaccinated. However, the symptoms he describes, bronchitis and pneumonitis, are better regarded as part of the normal disease syndrome than as complications. Pulmonary oedema was fairly common in haemorrhagic- and flat-type smallpox. Bronchopneumonia due to secondary bacterial infection sometimes occurred and could be serious in debilitated patients. In his long series of cases of variola minor, Marsden (1936) recorded only 7 cases of bronchopneumonia.

Although sometimes responsible for death, pulmonary complications were usually followed by complete recovery. However, coughing could have serious epidemiological consequences, if it occurred during the 1st week of disease, when the oral secretions were most highly infectious (see Chapter 4). A.R. Rao (personal communication, 1981) regarded cough associated with the sticky mucus of bronchitis as a relatively common symptom, especially in unvaccinated individuals. However, its epidemiological consequences were reduced if, as in the majority of cases, it did not become evident before about the 10th day of disease. Epidemiologists engaged in the global smallpox eradication programme regarded cough as a rare symptom in smallpox.

### Gastrointestinal System

Apart from vomiting and, less commonly, diarrhoea during the pre-eruptive stage, gastrointestinal symptoms were rare. Diarrhoea sometimes occurred in the 2nd week and acute dilatation of the stomach was observed, especially in infants, though only rarely (Rao, 1972). Extensive viral infection of the intestinal mucous membrane occurred in some severe cases, especially in flat-type smallpox.

In such cases, which were usually fatal, portions of the mucous membrane were passed as a tubular cast.

### Genitourinary System

Orchitis was uncommon (0.1% in Rao's series) and usually unilateral. This observation casts doubt on the suggestion of Phadke et al. (1973) that smallpox was the single most important etiological factor in obstructive azoospermia in India.

In haemorrhagic-type smallpox, bleeding into the pelvis of the kidney sometimes produced haematuria (see Table 1.6).

### Central Nervous System

Encephalitis was a relatively common complication of smallpox (about 1 in 500 cases in variola major (Rao, 1972) and 1 in 2000 cases in variola minor (Marsden, 1936)). It usually appeared between the 6th and the 10th day, when the rash was in the papular or vesicular stage. Encephalitis contributed little to the case-fatality rate of variola major but was an important factor in the few deaths which occurred in variola minor. Recovery, although sometimes slow, was usually complete.

According to a detailed review by Marsden & Hurst (1932), the symptomatology and the pathological findings in fatal cases of encephalitis associated with variola minor were indistinguishable from those of the encephalomyelitis which occasionally occurs after vaccination or in the late stages of measles. Clinical details are described in Chapter 7, for although it was a much rarer complication (in Madras, for example, 1 in 500 cases of smallpox and 1 in 100 000 cases of primary vaccination (Rao, 1972)), postinfection encephalitis was a much more significant feature of vaccination than of smallpox, since it was then the result of medical intervention in an otherwise healthy subject rather than a rare complication of a severe disease.

### SEQUELAE

In order of their frequency the sequelae seen in persons who recovered from smallpox were facial pockmarks, blindness, and limb deformities.

### Pockmarks

During the first few months after recovery from smallpox the sites of the scabs were abnormally pigmented, hypopigmented in dark-skinned persons and red or hyperpigmented in fair-skinned subjects (Plate 1.27A and B). As the skin regained its normal pigmentation, most cases of variola major, but few of variola minor, were seen to have pitted scars, called pockmarks, in the sites of some of the pustular skin lesions. These were depressed scars 2 mm or more in diameter, usually circular and varying in number from one (which would be difficult to ascribe to smallpox) to several hundreds (Plate 1.27C and D). They resulted from fibrosis in the dermis, and were much more common on the face because of the greater frequency of large sebaceous glands in the skin of the face (Bras, 1952b). Although the rash occurred on the scalp as well, relatively few pockmarks were seen there. In ordinary-type variola major the rash affected the sebaceous glands severely (Bras, 1952b) and permanent facial pockmarks occurred in 65–80% of survivors (Mack et al., 1970; Ježek et al., 1978d). The sebaceous glands were not affected in flat-type smallpox and the few patients who survived this type of infection were rarely severely pockmarked.

When secondary bacterial infection of the pustules occurred the resulting scarring was often more severe and the scars more irregular in shape than after an uncomplicated rash.

In variola minor the rash, though sometimes profuse, comprised shallow lesions that were usually restricted to the epidermis and only rarely involved the sebaceous glands—hence pockmarks were much less common in such cases. For example, Marsden (1936) recorded depressed scars in only 0.7% of his series of cases, although hyperpigmentation was present in about 11% of these fair-skinned subjects at the time of their discharge from hospital. Among persons with more deeply pigmented skins, hypopigmented spots sometimes occurred on the face or elsewhere for several months after recovery (Ježek & Hardjotanojo, 1980) but eventually disappeared.

The observation of facial pockmarks was an important epidemiological tool in smallpox eradication programmes in countries in which the disease was due to variola major, but in those in which variola minor prevailed pockmarking was too infrequent for such

surveys to be of epidemiological value (see Chapters 4 and 24).

### Blindness

Corneal scarring with consequent blindness sometimes followed the keratitis or corneal ulceration which was a rare complication of smallpox (though less uncommon in malnourished individuals). As Dixon (1962) commented, "Every writer on smallpox over the last 150 years has pointed out that in his experience the amount of blindness due to smallpox was much less than that quoted by previous authors". The explanation is probably that the authors quoted were almost always writing of conditions in Europe. During the last 150 years the level of nourishment and hygiene rose steadily among those who formed the subject of these publications, and, as remarked earlier, keratitis, corneal ulceration and corneal scarring rarely occurred in well-nourished patients. Blindness following smallpox remained a serious although uncommon complication in poorer countries (Plate 1.27C and D). Rao (1972) noted 60 patients with keratitis and/or corneal ulcer, of whom 24 had loss of vision in one eye and 1 in both eyes—an incidence of blindness of 0.45% among 5459 survivors. In Bangladesh, Hughes (WHO/SE/78.101) found blindness in 0.9% and corneal opacities in an additional 2.1% of patients examined 1–2 years after recovery from smallpox. All 4 cases of blindness and 7 of the 9 cases of corneal scarring occurred in unvaccinated subjects.

### Limb Deformities

As has been described earlier, osteomyelitis and arthritis were not uncommon complications of smallpox. Many cases resolved without permanent deformity. Because of the severity of the disease itself and the mild symptoms of joint involvement, skeletal manifestations were often missed during the acute infection and recognized years later in the form of bone shortening, flail joints, subluxations and gross bone deformities (Gupta & Srivasta, 1973).

## PROGNOSIS OF VARIOLA MAJOR

The prognosis of a case of smallpox had to be evaluated in terms of the likelihood of death and the possibilities of serious sequelae. In both respects, the prognosis of variola minor was almost invariably good; the vast majority of patients recovered and even facial pockmarks were an uncommon sequel. It is therefore necessary to consider the prognosis only in terms of variola major. As will be further elaborated in Chapter 2, there were geographical variations in the virulence of variola major virus, in terms of the usual case-fatality rates in different parts of the world, which during the period of the Intensified Smallpox Eradication Programme (see Chapter 10) seemed to be uniformly high in the Indian subcontinent and adjacent parts of western Asia and rather lower in Indonesia and western, central and eastern Africa.

### Calculation of Case-Fatality Rates

#### *How representative were hospital-based data?*

The calculation of the case-fatality rate in smallpox was not a straightforward matter. Most data (e.g., Rao, 1972; Guha Mazumder et al., 1975) were based on series of cases treated in hospitals; the question arises of how representative of the total spectrum of cases were those admitted to hospital. Rao's (1972) series was probably representative of cases in Madras; in a personal communication (1981) this author states that between 1961 and 1969, 80–90% of all cases in Madras were admitted to the city's Infectious Diseases Hospital, the proportion between 1965 and 1969 being almost 100%.

This was not true of other areas, especially where rural populations were involved. Koplan et al. (1978) investigated this problem in Bangladesh, from which smallpox had been eliminated in 1970 only to be reintroduced by refugees returning from India in 1972. Table 1.9 compares the age- and sex-specific case-fatality rates pertaining to 346 cases admitted to the Dhaka Infectious Diseases Hospital during the period March 1972 to April 1973 with those of 502 non-hospitalized cases diagnosed by specially trained surveillance teams in a rural area in the Noakhali District in south central Bangladesh during the period July 1972 to February 1973. The age and sex distributions of the two sets of data are very

similar; when the rates were applied to a standard Bengali population the overall case-fatality rates were only changed from 51% to 52% for the hospitalized patients and from 21% to 23% for the village patients, a highly significant difference between the two sets of data.

The explanation is complex and lies in a number of factors which would probably differ in importance in different places, but which must always be borne in mind when considering case-fatality rates based on hospitalized series of cases in countries in which smallpox was endemic. In Bangladesh, hospi-

tal admission reflected a high proportion of patients who were too ill to travel back to their villages or too sick to hide their illness within the community, whereas the village data essentially referred to every case in the community.

### Effects of Immunity

#### *Immunity after an attack of smallpox*

A person who had recovered from smallpox had a high degree of immunity to reinfection, which usually lasted throughout life, but

Table 1.10. Protection against challenge vaccination with vaccinia virus among persons who had recovered from smallpox<sup>a</sup>

<sup>a</sup> Variola major unless otherwise indicated.<sup>b</sup> Major reaction = primary type of reaction with vesicle 1 week after vaccination; or, more commonly, revaccination type, with vesicular or pustular lesion or area of induration surrounding a central scab or ulcer, after 6-8 days.<sup>c</sup> .. = data not recorded.<sup>d</sup> Data from Zikmund et al. (1978).<sup>e</sup> Data from Ježek et al. (1981).<sup>f</sup> Data from Vichniakov (1968).

second attacks did occasionally occur. Rao (1972) noted about 1 repeat attack per 1000 cases, the average interval between the attacks being 15–20 years. This refers to clinical disease, confirmed by laboratory investigation, in pockmarked persons. Serological examination of exposed contacts would probably have revealed that second subclinical infections were much more common; subclinical infection was not uncommon in vaccinated contacts (Heiner et al., 1971a). However, subclinical infections were of little epidemiological importance, except as boosters of immunity, since subjects with such infections did not transmit them.

Another measure of the persistence of resistance following smallpox was provided by determining the response of persons known to have had smallpox to challenge vaccination with vaccinia virus. Interpretation of the results (Table 1.10) is complicated by the fact that many of those who had had variola major had also been vaccinated, a procedure which enhanced immunity to challenge vaccination (Zikmund et al., 1978). A substantial proportion of persons exhibited a major response to vaccination as early as 1 year after recovery from variola minor, and even after variola major resistance to challenge vaccination was low in half the subjects tested 6–11 years after recovery from the disease. In variola major immunity to challenge vaccination persisted for much longer in those who had had a severe attack of smallpox than in those who had suffered only a mild attack (Vichniakov, 1968). As far as heterologous immunity is concerned, it appears that vaccination protected against naturally transmitted smallpox (see below and Chapter 7) rather more effectively than smallpox modified the response to vaccination. This may have been mainly due to the dose of virus and the manner of its implantation: a large dose introduced into the skin in vaccination and a small dose implanted on the respiratory mucosa in smallpox.

#### *Immunity after vaccination*

The effects of vaccination on preventing infection will be discussed in Chapters 7 and 11; here we are concerned with the effects of vaccination and/or revaccination on the severity of smallpox in vaccinated persons who did contract the disease. There are several difficulties in evaluating these effects. There were some patients who said that they had

been vaccinated (or revaccinated) but had no scar; Rao (1972) classed these as "unsuccessfully vaccinated". However, even in Madras some of these persons may have been successfully vaccinated, with vaccine of low potency applied over a small area of skin, leaving no scar; such misdiagnoses of vaccination status may account for the difference in prognosis between the "unvaccinated" and the "unsuccessfully vaccinated" in Rao's data (case-fatality rates in ordinary-type smallpox of 36.9% and 27.2% respectively). Among those with a vaccination scar there were other problems. First, did the scar really result from the replication of vaccinia virus in the skin? Secondary infection without viral replication could cause scars, especially when the rotary lancet was used with an unsatisfactory liquid vaccine. Secondly, how long ago did the last successful vaccination (or revaccination) occur? These questions could not always be accurately answered, but it is important to bear them in mind when considering the effects of vaccination on the prognosis of smallpox. Finally, the studies of Heiner et al. (1971a) showed that in endemic areas subclinical infection with variola virus occurred rather frequently among vaccinated persons, thus boosting their immunity.

Data published by Hanna (1913) from an outbreak of variola major in Liverpool, England, in 1902–1903, illustrate clearly the ameliorating effect of childhood vaccination on the severity of smallpox (Table 1.11). There was a striking difference between vaccinated and unvaccinated patients in all age groups, both in the spectrum of severity and in case-fatality rates. Protection waned with age—i.e., with increasing intervals since vaccination—but was substantial even in those aged more than 50 years.

Rao's data (see Table 1.2) confirm the extent of the protection against death provided by vaccination; the overall case-fatality rates in vaccinated and unvaccinated (including "unsuccessfully vaccinated") persons in his series were 6.3% and 35.5% respectively.

Hanna's conclusions on the duration of protection against death provided by vaccination, in those who got smallpox, is confirmed by data collected by Mack (1972), who analysed 680 cases of variola major occurring after importations of the disease into Europe and Canada during the period 1950–1971 (Table 1.12). The case-fatality rate was 52% in unvaccinated persons, 1.4% in those vaccinated 0–10 years before exposure, and only

<sup>a</sup> Based on Mack (1972).

11% in those vaccinated over 20 years before exposure. The contrast is even more striking if only the age group 10-49 years is considered: a case-fatality rate of 49% in the unvaccinated and one of 4.3% in those vaccinated over 20 years earlier.

Before 1967 it was a common practice in India, as it had earlier been in Great Britain and elsewhere, to make several insertions of vaccinia virus at adjacent sites. Early in the Intensified Smallpox Eradication Programme it was decided that vaccination should routinely be carried out on one site only (see Chapter 11), but some older data suggested that there was a correlation between protection and scar area (allowing for changes in the area with growth) and/or the number of insertions. For example, Hanna (1913) report-

ed that the mildest attacks of smallpox occurred in those with the largest scar areas, while at all ages the average scar areas of vaccinated contacts who did not get smallpox was substantially larger than in those who did. Likewise, Rao (1972) reported a case-fatality rate of 16.4% among 79 cases of ordinary-type smallpox in persons aged 0-9 years with only 1 scar, compared with no deaths among 70 cases in comparable individuals with 2, 3 or 4 scars.

#### Passive immunity

Apart from reports of the deliberate use of anti-orthopoxvirus serum for serotherapy, some information has been gathered on the effects of passive immunity resulting from the

vaccination of pregnant women during the incubation period of smallpox on the resistance of the fetus and the newborn child. Pregnant women were particularly susceptible to the effects of smallpox (see below), and abortion often occurred. Nevertheless, it was found that some women who had been vaccinated during the incubation period of their attack went to term and bore live babies who were usually resistant to smallpox, presumably because of passive immunization.

### Effects of Age

Smallpox affected persons of all ages; the age incidence of the disease in endemic countries reflected the particular epidemiological characteristics of the population at the time (see Chapter 4). Some relevant data on the relation of age to prognosis in cases of variola major occurring in unvaccinated subjects are provided in Tables 1.9 and 1.11; additional statistics from India are shown in Table 1.13 and data for Pakistan are given by Mack et al. (1970). All these figures accord with the general impressions of most epidemiologists with extensive experience of smallpox and are consistent with the usual pattern of age-related susceptibility to death from acute infectious diseases (Burnet, 1952). Mortality was very high (usually over 40%) in infants, fell to its lowest level in children, and then rose with increasing age. The low case-fatality rate in unvaccinated children is significant in that the famous variolators in Great Britain during the 18th century, such as

the Suttons, selected healthy children for this procedure (Razzell, 1977b), which may partly account for the low mortality it caused.

Such deaths as did occur in variola minor were predominantly in very young children. Suzart de Carvalho Filho et al. (1970) recorded an overall case-fatality rate of 0.8% in Brazil in 1968-1969, but the rate was 16.7% among patients aged less than 3 months and 2% in the age group 3-12 months (see Chapter 12, Table 12.16).

### Effects of Pregnancy

It is universally agreed that smallpox was more severe in pregnant women than in non-pregnant women or in men, irrespective of vaccination status. Table 1.14 sets forth the distribution of clinical types of smallpox in Rao's series, in pregnant and non-pregnant women and in men in the age group 15-44 years, according to vaccination status. Although pregnant women constituted only 11.6% of the series, 50% of the cases of haemorrhagic-type smallpox occurred among them, mostly in women who had been vaccinated in infancy; indeed, almost one-quarter of all cases of smallpox in pregnant women were of the haemorrhagic type. Flat-type smallpox was over twice as common among pregnant women (3.4% compared with 1.5%) whereas modified-type smallpox was less than half as frequent (9.4% compared with 21.2%).

The effects of smallpox on the fetus or the newborn infant were also severe (Table 1.15) but congenital smallpox was not often diag-

nosed among those born alive. Ten cases were recognized among the live births in Rao's series, but because their mothers had died many infants also died within a few days of birth and it was not determined whether they had smallpox or not. Smallpox caused premature termination of the pregnancy in 75% of women who got the disease during the early weeks of pregnancy and in 60% of those who contracted it after the fetus had become viable but before it had reached full term.

to some extent on the physiological factors just discussed, but clinical type provided much the best basis for the prognosis of individual cases. Haemorrhagic- and flat-type smallpox were almost always fatal and among cases of ordinary-type smallpox the extent of the rash (confluent, semiconfluent or discrete) was of prognostic value. Modified-type smallpox was very rarely fatal.

## DIFFERENTIAL DIAGNOSIS

### Clinical Type of Disease

Whether flat- or haemorrhagic-type smallpox developed in particular persons depended

The problems involved in the diagnosis of smallpox during an epidemic or in a situation in which the disease was endemic were of a

different nature from those in suspected importations into non-endemic countries or regions. There were three elements in the diagnosis: clinical, epidemiological, and laboratory. No one diagnostic approach was always sufficient in itself. The clinical diagnosis of ordinary-type smallpox after the rash had developed was not difficult, and most cases were of this kind. But there were often patients in whom an accurate diagnosis could not be made on clinical grounds alone, at any rate at the first examination, early in the course of the disease. In such cases the epidemiological circumstances of the suspected case often provided a valuable lead. Nor was it wise to trust implicitly a positive report from the laboratory, if it ran counter to clinical and epidemiological evidence. Like everyone else, laboratory workers sometimes made mistakes, and clerical errors were always a possibility.

The clinical diagnosis of the great majority of cases of smallpox rested on the characteristic features of the pre-eruptive fever, the order of appearance of the rash (first on the face, then on the forearms, trunk and lower limbs), the evolution of the individual lesions, from macule to vesicle and pustule, and the appearance and feel of the vesicle and pustule. Furthermore, the lesions on any particular part of the body were all at more or less the same stage of development. The distribution of the skin lesions was also of great diagnostic value, with relatively few lesions on the trunk but many on the face and arms (more on the extensor than the flexor surfaces) and on the lower limbs, and on the palms of the hands and the soles of the feet. The major difficulties in differential diagnosis of ordinary-type smallpox arose in cases modified by vaccination, in which the lesions were often sparse and abnormal in appearance and underwent an accelerated course of evolution.

The diagnosis of flat-type smallpox was also relatively straightforward, but haemorrhagic-type smallpox, especially the early subtype and both forms in the early stages, was usually impossible to diagnose without laboratory assistance, and the diagnosis was often missed in non-endemic situations in which smallpox was not thought of by the attendant physician.

Diagnosis of smallpox in the pre-eruptive stage was impossible on clinical grounds alone, although it would have been suspected if epidemiological considerations (exposure to a known case, lack of vaccination) had been suggestive. The differential diagnosis of

smallpox at this stage of the disease will therefore not be discussed here.

### Ordinary- and Flat-Type Smallpox

The diseases involved in the differential diagnosis of ordinary- and flat-type smallpox were essentially those causing fever with rash.

#### *Human monkeypox*

Although a rare disease, human monkeypox ranks first among the diseases that might be confused with smallpox, because differential diagnosis was impossible on clinical grounds alone, although gross lymphadenopathy was found in most cases of monkeypox and not in smallpox (see Chapter 29). In the field, diagnosis depended on the occurrence of a disease indistinguishable from ordinary-type smallpox in the appropriate epidemiological situation: a particular geographical area (western and central Africa), no endemic smallpox, and the appropriate environmental surroundings (a small village in a tropical rain forest). Laboratory confirmation was essential, either by recovery of the virus from lesion material or retrospectively by appropriate serological tests.

#### *Chickenpox*

This disease of world-wide occurrence was the single most important infection to be considered in the differential diagnosis and was particularly important in three circumstances: in countries in which variola minor was endemic, in vaccinated individuals, and in situations in which chickenpox occurred rather frequently in adults, often as a severe disease, as in several parts of India. For example, in post-eradication searches in India in 1976, 63% of the "suspected smallpox" cases were in fact cases of chickenpox (Ježek et al., 1978e).

In the usual case of chickenpox the nature, distribution and evolution of the rash are quite distinctive (Plate 1.28). The skin lesions in chickenpox are much more superficial than they were in smallpox. They appear in "crops" so that at any time lesions of various ages may be found on the same part of the body and their distribution is "centripetal" (denser on the trunk than the face and extremities) rather than "centrifugal", as in smallpox.

**Plate I.27.** Sequelae of smallpox. Shortly after recovery the sites of pustules are usually depigmented in dark-skinned subjects (A) or red in fair-skinned subjects (B). Most cases of variola major leave facial pock marks, which may be deeply pigmented (C); blindness is a rare complication (C and D). (B from Herrlich et al., 1967.)

**Plate 1.28.** Chickenpox. On the 3rd day of rash (**A**, **B** and **C**) pocks are at different stages of development: papules, vesicles, pustules and scabs. On the 7th day of rash (**D**) all pocks are scabbed. There are many lesions on the trunk (**B**) and few on the limbs.

**Plate 1.29. A:** Measles. There is a blotchy generalized rash, as well as a runny nose and sore eyes. **B:** Secondary syphilis. The rash had a different distribution from that of smallpox, did not feel "shotty" and did not progress to pustules and scabs as in smallpox. (From Lambert & Farrar, 1982). **C:** Erythema multiforme.

**Plate I.30.** A and B: Drug eruptions, which sometimes occurred in patients with smallpox. C and D: Meningococcal septicaemia, which could be difficult to differentiate from early haemorrhagic-type smallpox. (B, C, D from Lambert & Farrar, 1982.)

Difficulties arose with severe chickenpox in adults (White, 1978), a disease found especially in some parts of India (Kerala, Tamil Nadu (formerly Madras State), and West Bengal). Indeed, some severe cases of chickenpox in adults were associated with such an extensive rash, including lesions on the palms and soles, that it was impossible to be certain at any stage of the disease as to whether it was chickenpox or smallpox. During the eradication programme, all such cases were regarded as smallpox and appropriate control measures were undertaken. Sometimes the lesions in this type of chickenpox were haemorrhagic, and it was in these cases that the rate of development of the rash and its distribution were important diagnostic features.

Such severe cases of chickenpox have always been rare. Diagnostic problems occurred more frequently between attacks of chickenpox of ordinary severity and mild, particularly vaccine-modified, attacks of smallpox. In vaccine-modified smallpox the lesions were often superficial, not "shotty"; they dried up quickly with a small scab and left scars very little different from those of chickenpox. Differential diagnosis was often impossible on clinical grounds alone; laboratory confirmation was essential.

Since they had the same seasonal incidence, smallpox and chickenpox might sometimes have been expected to occur concurrently in the same patient. Sarkar et al. (1976) report 3 such cases from a refugee camp near Calcutta in 1972, in males aged 15, 30 and 60 years respectively, all with vaccination scars. All the patients survived, the clinical course of each disease being unaffected by the other. The diagnosis of smallpox was confirmed in every case by the examination of material from variola-like lesions, and varicella virus was detected by electron microscopy in vesicle fluid from a chickenpox-like lesion in the one case that was examined by this technique.

### *Tanapox*

This poxvirus disease occurs as a zoonosis in parts of Kenya and Zaire, and probably elsewhere in Africa (see Chapter 29). The lesions are usually single, and few in number if they are multiple. They are nodular rather than pustular and evolve much more slowly than the lesions of smallpox. However, when first seen, such lesions could be confused with those of mild smallpox in a vaccinated subject.

The slow course and absence of pustulation would subsequently clarify the diagnosis. Electron microscopic examination of lesion material reveals virions similar to those of variola virus. However, tanapox cannot be cultivated on the chorioallantoic membrane.

### *Measles*

In the first 2 days of the rash, before vesicles developed, the most likely cause of confusion was measles (Plate 1.29A), and this difficulty could persist for several more days in flat-type smallpox, although the severity of this disease was much greater than that of measles. The presence of Koplik's spots was, of course, diagnostic of measles, and in any case the difficulty disappeared as the rash evolved. Historically, measles did not present a problem in countries with endemic smallpox, but in non-endemic countries an early case of smallpox was sometimes diagnosed as measles, with possibly serious consequences in terms of secondary cases. On the other hand, in countries in which smallpox was endemic, physicians were often prone to diagnose all outbreaks of rash associated with deaths as smallpox and to report them as such to the health authorities. Some of these outbreaks later proved to be due to measles.

### *Syphilis*

Earlier writers, e.g., Councilman (1907) and Ricketts (1908), paid considerable attention to syphilitic rashes as presenting a problem in differential diagnosis. With the advent of penicillin and the consequent reduction in the incidence of syphilis—especially of secondary syphilis—in the developed countries, the disease has ceased even to be mentioned by writers, such as Christie (1980), dealing with the general domain of infectious diseases. However, in African countries and India secondary syphilis remained a disease to be considered in the differential diagnosis of smallpox, up to the time of eradication. The roseolar and papular syphilitic rashes (Plate 1.29B) varied in size and distribution and felt different from those of smallpox. The individual lesions were sometimes hard, but they could not be rolled between the thumb and forefinger, to give the "shotty" feel characteristic of the smallpox vesicle. Neither could they be "split" by passing a needle horizontally through the lesion, as could the vesicles of smallpox. The

distribution was also different; if there were a profuse rash on the face, there would also be an equally dense rash on the chest and abdomen and the toxæmia would have been too slight for a case of smallpox with such a rash. Finally, the diagnosis would be clinched by the fact that the papules of syphilis did not evolve further, to vesicles and pustules, like those of smallpox.

### *Erythema multiforme*

This disease (Plate 1.29C) could cause difficulties at any stage of the rash; the distribution of lesions is sometimes very like that of smallpox. In both diseases the patient could be quite ill and have a profuse vesicular eruption particularly affecting the extremities. However, the history is completely unlike that of smallpox: the onset of symptoms and rash tend to coincide and the rash evolves very rapidly to the vesicular stage. Further, erythema multiforme is almost always accompanied by stomatitis, and often by conjunctivitis and urethritis.

In severe cases there could be confusion with flat-type smallpox, since the vesicles were occasionally soft, superficial and flat, individually resembling those of flat-type smallpox. They sometimes coalesced and produced large bullae, also seen in some cases of severe smallpox. The degree of malaise was usually not like that seen in flat-type smallpox, where the patient at this stage had only about 48 hours to live, but the most important difference was in the speed of evolution of the rash in the two diseases. In smallpox with this skin picture the patient would have been ill and getting progressively worse for at least 10 days and the vesicular eruption would have only just fully emerged; in erythema multiforme the rash develops with the onset of constitutional symptoms and evolves rapidly to the vesicular stage.

### *Lesions due to vaccination*

Generalized vaccinia, described in Chapter 7 (see Plate 7.7), rarely caused confusion; the history of vaccination and the nature and distribution of the rash differed substantially from what was found in smallpox. However, problems of precise diagnosis sometimes arose in smallpox contacts who had been vaccinated during what turned out to be the incubation period of smallpox. They usually showed a positive take at the vaccination site and often

a modified rash, which could have been caused by variola or vaccinia virus. Operationally, all such cases were regarded as smallpox from the point of view of management. Precise diagnosis could be made by the culture of virus from several of the vesicles or pustules.

### *Drug eruptions*

Although less important in countries in which smallpox was still endemic, drug eruptions (Plate 1.30A and B) were an important diagnostic problem in countries in which smallpox had been eradicated years before and doctors rarely considered the possibility of the disease. Many instances exist in which the rash of an imported case of smallpox, and sometimes the rashes of second generation cases deriving from it, were diagnosed as drug rashes, since the sick patients had customarily been treated with some kind of drug for the pre-eruptive fever. The diagnosis usually became quite clear with the passage of time and the evolution of the rash, but vaccine-modified smallpox could continue to mislead the physician if he had never considered smallpox as a possible diagnosis.

In endemic countries in recent years, since a wide variety of drugs have become available, cases of smallpox and drug eruption sometimes occurred coincidentally. Rao (1972) described a case in which the drug rash completely obscured that due to smallpox and the diagnosis was only made when variola virus was recovered from some "seeds" extracted from the palms of the hands.

### *Rashes due to other causes*

There are few diseases characterized by a rash that did not at some time suggest a diagnosis of smallpox, occasionally with dramatic effect in non-endemic countries. Acne, scabies and insect bites may be mentioned as examples. Coxsackievirus infections could pose a problem (Mukherjee et al., 1976), and in countries in which both diseases were endemic, dengue haemorrhagic fever and other arbovirus infections associated with a rash were sometimes initially diagnosed as smallpox.

## **Haemorrhagic-Type Smallpox**

Haemorrhagic-type and flat-type smallpox were sometimes associated with a severe

Table 1.16. Alternative diagnoses in suspected but unconfirmed cases of smallpox

shock-like condition, loss of muscle tone and a peculiar state of apprehension and mental alertness that were said to be unlike the manifestations of any other infectious disease. The occurrence of a petechial rash, especially in the groin and along the flanks to the axillae, was regarded as diagnostic of smallpox, since other forms of febrile purpura, due to meningococci or other organisms, did not have such a localized and symmetrical distribution; but an accurate diagnosis was impossible without laboratory aid. The literature on outbreaks following the importation of smallpox into non-endemic countries (see Chapter 23) is replete with instances in which the index case or sometimes a first generation case, presenting as an acutely fatal case of haemorrhagic-type smallpox, was almost always misdiagnosed as meningococcal septicaemia (Plate 1.30C and D) or acute leukaemia. However, meningococcal bacteraemia is usually more rapidly lethal than was haemorrhagic-type smallpox; acute leukaemia is less rapid.

Erythematous rashes on the face and later on the arms and trunk sometimes suggested the diagnosis of toxic scarlet fever, but the early rash in haemorrhagic-type smallpox was a diffuse not a punctate erythema, the temperature was lower than in severe scarlet fever and the tongue and fauces were practically normal.

Even in endemic areas, and at times when variola major was a common disease, it was very difficult to diagnose very severe smallpox, whether of the haemorrhagic or of the flat type, in its early stages. It can be readily understood why the diagnosis was so often missed in non-endemic countries.

### Effects of Prior Vaccination on Symptomatology

From the diagnostic point of view it was important for physicians to appreciate that there was great individual variation in the extent to which vaccinia immunity persisted. The person presenting with symptoms suggestive of flat-type smallpox, who had had a successful primary vaccination within 5 years, was unlikely to be suffering from this disease; the probability of another diagnosis should therefore have been seriously considered. On the other hand, the presence of signs or symptoms suggestive of a very mild attack of smallpox should not have led the doctor to discount the diagnosis even in the face of an apparently successful vaccination within a year. It was also important to remember that exceedingly mild smallpox, even variola sine eruptione, could occur in persons who had no evidence of ever having been successfully vaccinated.

### Alternative Diagnoses

Several authors have summarized alternative diagnoses that have been made in suspected but unconfirmed cases of smallpox. Table 1.16 lists final diagnoses made in cases of suspected smallpox in situations in which variola major was the expected form of the disease (England and Wales, 1946-1948; India, 1976) and in those in which the endemic disease was variola minor (Somalia, 1977-1979). The overriding importance of chickenpox is apparent in all series. Marsden (1936) also reported that chickenpox was by far the commonest disease to be initially mistaken for variola minor in England (31% of 994 cases of suspected but unconfirmed smallpox). Other conditions suspected to be smallpox included almost all diseases that produced a rash.

### LABORATORY CONFIRMATION OF SMALLPOX DIAGNOSIS

Laboratory methods played a crucial role in the global smallpox eradication programme; indeed, eradication could not have been confidently certified to have been achieved without their use. A detailed historical description of the laboratory methods used for the diagnosis of smallpox is presented in Chapter 2 and an account of the development of laboratory support for the Intensified Smallpox Eradication Programme is given in Chapter 10.

As well as being of critical importance in the global smallpox eradication programme, laboratory methods were also useful for the confirmation of clinical diagnoses. Indeed, although laboratory workers could make mistakes, the recovery of variola virus from a skin lesion was usually regarded as conclusive evidence that a particular patient was or had been suffering from smallpox. Such confirmation was rarely sought in endemic countries when smallpox was a common disease. Any doubtful case was always regarded as smallpox; containment and vaccination procedures operated independently of and were initiated before laboratory confirmation. However, laboratory confirmation or refutation of suspected smallpox was a valuable procedure in non-endemic countries and in smallpox-free regions of the endemic countries as eradication approached.

If an electron microscope was available, the examination of material from vesicles, pus-

tules or scabs, examined by the negative staining technique, could give a rapid presumptive diagnosis of poxvirus, or sometimes herpesvirus, infection. Definitive diagnosis depended on the isolation of the causative virus on the chorioallantoic membrane of the developing chick embryo and its further characterization, if necessary, by biological tests. Usually the character of the pocks produced on the chorioallantoic membrane was distinctive enough for the diagnosis of variola, vaccinia, monkeypox or herpesvirus infection to be made (see Chapter 2).

In the period before the Intensified Smallpox Eradication Programme was launched, gel-precipitation tests were employed extensively in some national programmes (e.g., in India; Basu et al., 1979), and by laboratories that did not have an electron microscope. With adequate amounts of recently collected vesicle fluid it was an accurate and rapid test (World Health Organization, 1969a; A.W. Downie, personal communication, 1981), and when antivariella serum was employed in parallel tests it could be used to differentiate smallpox from chickenpox (Brunell et al., 1971; A.R. Rao, personal communication, 1981).

### TREATMENT: PROPHYLACTIC AND CURATIVE

No disease better illustrated the adage "Prevention is better than cure" than smallpox. Nevertheless, until 1975 millions of persons were infected with variola major virus and, as the foregoing description of its clinical features bears witness, it was a horrible disease with a high case-fatality rate. Any treatment that would ameliorate the severity of the disease in those who were infected would have been welcomed.

In this section, treatment administered after exposure and thus during the incubation period is called "prophylactic" and treatment given after the development of symptoms "curative". Three procedures were used or investigated: vaccination after exposure, immunoprophylaxis and immunotherapy, and chemoprophylaxis and chemotherapy.

#### Vaccination during the Incubation Period

The sheet anchor of smallpox control during the Intensified Smallpox Eradication

Programme was surveillance and containment (see Chapter 10). Containment was possible because vaccination provided protection against infection for those who had not already been infected with variola virus. However, vaccination must also be discussed as a form of prophylactic treatment, for it also modified the progress of the disease in persons vaccinated during the first few days of the incubation period. The precedent for this concept was Pasteur's demonstration of protection against rabies by vaccination during the incubation period. The different time-scales of the pathogenesis of vaccinia and variola (see Fig. 1.3 and Fig. 3.1 of Chapter 3) provided hope that such prophylactic treatment, if carried out during the first week of the incubation period of smallpox, might ameliorate or sometimes abort the disease. Precise data were difficult to obtain, because it was rarely known whether or when a contact had actually been infected with variola virus. Unless sophisticated serological tests had been carried out (and this was never done) it would have been impossible to differentiate between a person sustaining only vaccination and one who had also been incubating smallpox but in whom that infection had produced no symptoms. However, all observers agree that persons in whom smallpox developed a week or more after primary vaccination often had a modified attack. Dixon (1962) summarized his review of the older literature by saying that "at least 50% of cases where successful primary vaccination had occurred during the first week [of the incubation period] will get some vaccine-modification and reduction of severity, whereas when done at a later period the number showing such modification is not likely to be over 20%". In fact, on theoretical grounds the degree of modification might be expected to be highly dependent on the exact timing of infection with variola virus and vaccination; the more nearly these corresponded, the greater was the degree of protection. Without distinguishing the timing of primary vaccina-

tion, Rao (1972) observed a frequency of modified-type smallpox of 8.8% among those given primary vaccination after exposure, compared with 1.0% among unvaccinated patients.

Successful revaccination would have been expected to be even more effective, because of the accelerated immune response.

### Immunoprophylaxis and Immunotherapy

Although the procedure was rendered superfluous by the development of effective measles vaccines, measles could be aborted or ameliorated by the administration of immune gamma-globulin during the first 7 days of the incubation period (Janeway, 1944). During the 1960s some experimental work was carried out in animals (see Chapter 3), and a few trials were made in human beings, to determine whether immunoprophylaxis or immunotherapy might be useful in smallpox.

The most comprehensive trials were carried out in Madras (Kempe et al., 1956, 1961). Immune gamma-globulin, prepared from the serum of recently vaccinated adults (not smallpox convalescents) was administered to close contacts of smallpox cases, most of whom were also vaccinated or revaccinated at the same time. The results of these and other trials (Marennikova, 1962), summarized in Table 1.17, indicate that if given during the incubation period vaccinia-immune gamma-globulin provided protection additional to that expected from vaccination at that time. The greater potency against variola virus of homologous antiserum from smallpox convalescents (Downie & McCarthy, 1958; Downie et al., 1961b) might have been expected to give even better results, but no trials were ever made with such sera. In any case vaccinia-immune or variola-immune gamma-globulin were available in such small quantities that they could only have been used in unusual situations. However, vaccinia-immune gamma-globulin did appear to have a place in the prevention and treatment of vaccination

Table 1.17. Seroprophylaxis of smallpox: effects of vaccinia-immune gamma-globulin on the occurrence and severity of smallpox in vaccinated case contacts

complications in some especially susceptible individuals (see Chapters 7 and 11).

### Chemoprophylaxis and Chemotherapy

It is not surprising that orthopoxviruses, being the largest and most complex viruses, were among the first for which antiviral agents were developed that were effective in inhibiting viral replication in cells (see Chapter 2). Some of these drugs also had activity against orthopoxvirus infections in mice and they were subsequently tested for the treatment and chemoprophylaxis of smallpox. The results were disappointing, in that none was effective in treatment, and chemoprophylaxis was of marginal value only and did not compare in effectiveness with the vaccination of contacts.

#### *Thiosemicarbazones for chemotherapy*

The effectiveness of certain thiosemicarbazones in the treatment of tuberculosis led to the demonstration by Hamre et al. (1950) that some thiosemicarbazones reduced the mortality of mice inoculated with vaccinia virus. This led to the testing by pharmaceutical companies of many different thiosemicarbazones, two of which (*N*-methylisatin  $\beta$ -thiosemicarbazone (metisazone (methisazone)) and 4-bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone (M & B 7714)) appeared to be particularly effective against variola in mice (Bauer & Sadler, 1960; Rao et al., 1965). Clinical trials for the treatment and prophylaxis of smallpox were car-

ried out in Madras (see reviews by Bauer (1972) and Rao (1972)).

Both drugs were only slightly soluble and were given as tablets or as a micronized preparation in syrup. The main side-effects were nausea and vomiting, which were sometimes severe. Rao et al. (1966a, 1969b) carried out double-blind trials of both thiosemicarbazones (Table 1.18). The only apparent differences between the treated and control groups were small reductions in the already low case-fatality rates in vaccinated subjects. However analysed, there were no significant differences in case-fatality rates between the unvaccinated treated subjects and the controls; nor were there any significant differences in symptomatology among the small number of cases of ordinary-type smallpox whom it was possible to treat as early as the 5th day of disease (2nd day of rash).

#### *Thiosemicarbazones for chemoprophylaxis*

Clearly, these thiosemicarbazones were useless for the treatment of smallpox. However, Bauer et al. (1963) had claimed impressive results in chemoprophylaxis with metisazone in a trial in Madras. Most of the case contacts had been vaccinated during infancy and again shortly after detection of the index cases. Among 1100 subjects treated with metisazone there were 3 cases of smallpox and no deaths. Of 1126 controls not given the drug, 78 developed smallpox and 12 died. The result was hailed enthusiastically: "...if further experience of this substance leads to equally favourable conclusions, the work...will perhaps rank as the most significant advance

Table 1.18. Case-fatality rates in patients treated with either of two thiosemicarbazones and placebo\*

### A Comment on Chemoprophylaxis in Smallpox

"The major drawback to routine use of the drug [metisazone] is the frequency of often severe nausea and vomiting which occurs in not less than 25% and more often in two-thirds or more. In presently endemic countries, use of the drug is wholly impractical, not only in terms of acceptance on the part of the population, but because of the logistics involved in giving it. It has been difficult enough to persuade health administrators of the need for immediate investigation and control of all outbreaks and even more difficult to establish the mechanics for doing this properly. Use of methisazone would require not only administration of the drug but repeat visits to determine whether vomiting had occurred and, if necessary, repeat administration of the drug. This cannot be considered.

"In the non-endemic developed countries, one could more easily cope with the logistics of administration. It is noted, however, that vaccinia immune globulin has been shown to have a protective efficacy of the same order of magnitude as methisazone but without the associated toxic side effects." (D.A. Henderson, unpublished report, December 1970.)

in smallpox control since the days of Jenner" (*Lancet*, 1963). Such a comment was perhaps pardonable in Great Britain at a time when there were rather frequent importations of variola major from the Indian subcontinent. Statements in the Indian press, such as "at last a drug has come to replace the much dreaded vaccination" (quoted by Rao, 1972), were more serious in their implications for the control and eradication of smallpox.

There were major defects in the design of this trial: treatment and control groups were not allocated at random, contacts were not visited daily, and assessment of the taking of the drug (which caused nausea and vomiting) was made by questioning at a second visit 2 weeks after supplies of it had been distributed. Further trials with metisazone gave variable but mostly favourable results, which are summarized in Table 1.19. Rao et al. (1966b) reported a less favourable but still significant result with unvaccinated contacts given M & B 7714 as a chemoprophylactic drug.

The overall conclusion is that, given prophylactically, metisazone did exert some protective effect, but its administration was often associated with severe nausea and vomiting. Health administrators considered its use in countries in which smallpox was still endemic in the late 1960s and early 1970s as "wholly impractical" (see box) in terms of acceptability by the populations concerned and the logistics of administering it. In non-endemic countries these difficulties would be less serious but in these situations vaccinia-immune globulin, which had a protective effect of the same magnitude as metisazone, without toxic side-effects, was available. Prompt vaccination or revaccination of contacts remained the sheet anchor of prophylaxis until smallpox was finally eradicated.

#### Cytosine arabinoside

In an uncontrolled trial in Bangladesh, Hossain et al. (1972) reported promising

Table 1.19. Summary of results of thiosemicarbazone prophylaxis in smallpox

results with cytosine arabinoside in the treatment of variola major. However, subsequent controlled studies in both variola major (Monsur et al., 1975) and variola minor (Dennis et al., 1974) provided no evidence of any effect on either the mortality (in variola major) or the clinical progression of the disease. Nor was the related drug, adenine arabinoside, of any use (Koplan et al., 1975).

### Symptomatic Treatment

In the absence of any effective therapy for established cases of smallpox, treatment was symptomatic and demanded above all good nursing care, which put great demands on the devotion and skill of the nursing staff. In the crowded smallpox hospitals in endemic countries most nursing care was in fact provided by

members of the patient's family, who often came to stay in the hospital.

In endemic countries, in which hospital facilities were often poor, patients were usually better looked after at home in their village surroundings. Koplan et al. (1978) showed that the case-fatality rate was substantially higher in hospitals than in village surroundings, mainly because only the more severe cases, often in persons without local family support, were admitted to hospital, and devoted family care was better than the nursing provided in grossly overcrowded hospitals. Another reason for encouraging treatment at home during the Intensified Smallpox Eradication Programme was the frequency with which smallpox was transmitted to other patients in hospitals, which often left much to be desired in terms of their overall administration and management of other patients, visitors and staff.

**Day 5**

**Plate I.8.** Fifth day of rash. Almost all the papules have now become vesicular or pustular, the truly "vesicular" stage usually being very brief. Some of the lesions on the upper arm show early umbilication.

**Day 6**

**Plate I.9.** Sixth day of rash. All the vesicles have now become pustules, which feel round and hard to the touch ("shotty"), like a foreign body.

**Day 7**

**Plate I.10.** Seventh day of rash. Many of the pustules are now umbilicated and all lesions now appear to be at the same stage of development.

**Day 8**

**Plate I.11.** Eighth day of rash. This case is now clearly classified as discrete ordinary-type smallpox. In the confluent subtype of ordinary-type smallpox the lesions would have been confluent on the face and forearms (see Plate I.18); in the semiconfluent subtype they would have been confluent on the face but not on the forearms.

**Day 9**

**Plate I.12.** Ninth day of rash. The pustules have reached their maximum size and are becoming flattened.

**Day 13**

**Plate I.13.** Thirteenth day of rash. The lesions are now scabbing, but the eyelids are more swollen than at earlier times. There is no evidence of secondary bacterial infection of the skin lesions.

**Day 20**

**Plate I.14.** Twentieth day of rash. The scabs have separated except on the palms of the hands and the soles of the feet, leaving depigmented areas.

## The Eruptive Stage

Chapter 3 concludes with an integrated picture of the pathogenesis of smallpox, which was a generalized viral infection with no recognizable primary lesion but with a viraemia whose onset was manifested clinically by the pre-eruptive fever, followed a few days later by the development of a focal eruption on the mucous membranes and skin. Following the example of Ricketts (1908), our description of the clinical features of smallpox is in large part based on illustrations, using a series of colour photographs taken for WHO during the smallpox eradication programme in Pakistan. The subject was a 9-month-old unvaccinated male infant in whom the onset of fever was recorded 1 day before the rash first appeared. He suffered from the commonest form of smallpox—discrete ordinary-type—and recovered without complications. Daily photographs were taken, until recovery was complete, of the entire subject and of face, trunk, arms and legs. Only a limited selection of these can be reproduced here, but they serve to illustrate the nature, evolution and distribution of the rash of smallpox. The temporal succession will be described in terms of the day of rash.

### *Order of appearance of the focal lesions*

The lesions on the mucous membranes (the enanthem—Plate 1.3C) were the first to appear, and they were visible on the tongue and palate, as minute red spots, about 24 hours before the appearance of rash on the skin. Lesions also occurred at this time lower down in the respiratory tract, and some patients, who complained of sore throats during this stage, had an enanthem on the pharynx.

The rash usually appeared between 2 and 4 days after the onset of fever as a few small macules ("herald spots") on the face, especially on the forehead (Plate 1.4). In a few cases the rash was first seen on the forearms or some other part of the body. Lesions then appeared on the proximal portions of the extremities, on the trunk, and lastly on the distal portions of the extremities. However, the lesions appeared in such quick succession that it was difficult to follow the timing of their occurrence on the different parts of the body, and only rarely did a patient notice this order of appearance and give such a history. Usually the rash had appeared on all parts of the body within 24 hours. Additional lesions often

appeared during the next one or two days (compare Plates 1.4, 1.5 and 1.6) but normally no fresh lesions appeared after that (Plate 1.7).

In a particular area of the body surface all the lesions were at about the same stage of evolution, although of different sizes, because the rash developed essentially as a single "crop". However, up to the 3rd day, because of the order of their appearance, there were sometimes papules on the face and macules on the legs and similarly, after scabbing had started, lesions might be scabbing on the face and still be pustular on the legs. By the 11th day many of the scabs had come off the face, the temperature had fallen and the patient felt much better. Separation of the scabs proceeded in the same order as the macules and vesicles had appeared, from the face and scalp to the trunk, arms, hands, legs and feet. By the 17th day, only the lesions in the thick-skinned palms of the hands and soles of the feet remained (Plate 1.16).

### *Evolution and distribution of the enanthem*

The enanthem evolved rapidly, because of the absence of a horny layer in the stratified epithelium of the pharynx. The minute macules became papular and vesicular and then broke down before the 3rd day (Plate 1.3C), liberating large quantities of virus into the saliva. By the 10th day they had almost healed.

The visible parts of the oropharynx most likely to show lesions were the hard palate, the tip and edges of the tongue and the pillars of the fauces. Different patients showed remarkable variations in the extent of the enanthem; in cases of equal severity the lesions were sometimes few or absent, or the mouth and throat might have been covered by a confluent enanthem that extended to the larynx and trachea. Although not as spectacular as the rash, the pharyngeal lesions were of great importance epidemiologically, as they constituted the major source from which virus was transmitted to other persons (see Chapter 4).

### *Evolution of the skin lesions*

By the 2nd day of rash the macules were raised and usually described as "papules". Reference to the histopathology indicates that this term was really a misnomer; they were raised above the skin surface because of the effusion of fluid into the tissue spaces and were in fact early vesicles (Plates 1.5 and 1.6).

G. BRAS

**Plate 1.15.** Section of a skin lesion on the 6th day of rash. Ballooning degeneration of the cells of the lower part of the epidermis has produced a loculated vesicle which is becoming pustular. The keratohyalin and horny layers form the roof of the vesicle; at the base the dermis is undamaged—there will be no scarring after healing. The central depression associated with the hair follicle on the extreme right would produce loculation of the lesion. (Haematoxylin and eosin, x 50.)

By the 4th or 5th day they were obviously vesicular, containing at first an opalescent fluid, which became opaque and turbid in another 24–48 hours (Plates 1.7–1.9).

By the 7th day all the skin lesions were pustules (Plate 1.10) and between then and the 10th day they matured and reached their maximum size (Plates 1.11 and 1.12). By about the 11th day resolution started and the lesions flattened (Plate 1.13). The fluid was slowly absorbed, and by the end of the 2nd week the central portion hardened and finally a scab or crust formed, which later separated, leaving a depigmented area (Plate 1.14).

The palms of the hands and the soles of the feet, because of the very thick stratum corneum, were characterized by the persistence of lesions long after these had scabbed elsewhere. On the soles of the feet especially they had a very characteristic appearance (Plate 1.16). The thick cuticle lay over them and they did not protrude from its level surface, through which the disc-like scabs could be clearly seen. These lesions were called “seeds” and were often artificially removed with a

needle in attempts to hasten discharge from the hospital, where patients were usually held until the last scab had separated.

The evolution of the rash can best be appreciated by scanning the series of colour plates provided, which show the lesions daily from the 1st until the 9th day (Plates 1.4–1.12), and then on the 13th (Plate 1.13) and 20th days (Plate 1.14).

#### *Characteristics of the individual lesions*

Variolous skin lesions, which usually had only a barely perceptible erythematous areola around them, were traditionally held to have three distinctive characteristics: loculation of the cavity of the vesicle, its umbilication, and the solidity and hardness of the lesion.

*Loculation.* The reasons for loculation are clear from a consideration of the histopathology (Plate 1.15); it used to be determined in cases of smallpox by piercing the vesicle and observing that the fluid contents could not be completely emptied through the wound. However, this was a rather inefficient clinical

### Histopathology of Skin Lesions

In order properly to appreciate the clinical features of the skin lesions it is necessary to consider their histopathology. This is described in detail in Chapter 3, but it is convenient to summarize the main features of the lesions here. Plate 1.15 represents a section of part of a skin lesion in which vesiculation was beginning. The lesion occupied the whole depth of the epidermis, the deeper layers of which provided the floor and the cuticle (stratum spinosum, keratohyalin layer and horny layer) the roof. At the centre the floor was thin and as the lesion grew the deeper layer of basal cells lysed and the dermis then formed the base of the vesicle. But ordinarily (except in the face, where the numerous sebaceous glands complicated the picture) the lesion was contained within the epidermis. As infected cells became necrotic and fluid accumulated, the tissue split, the columns of epidermal cells being forced apart irregularly, so that the fissures were usually perpendicular to the surface and the vesicle consisted of several separate compartments or locules. As cellular necrosis and polymorphonuclear cell infiltration proceeded the fluid became turbid and the lesions pustular, but their turbidity was due to the extensive tissue destruction by the virus and a leukocytic reaction to this; the pus was not associated with bacterial infection.

test, in that it was readily demonstrable in cases in which there was little doubt about the diagnosis but equivocal in cases in which doubt might arise because the vesicles were small or soft. It was rarely used for differential diagnosis by workers engaged in the global smallpox eradication campaign.

*The "feel" of the lesion.* The skin lesions of smallpox were usually described as "shotty". Although as papules they projected little above the surface, they could be rolled between the thumb and forefinger and felt like hard round foreign bodies embedded in the epidermis.

*Umbilication.* This term refers to the central depression, of varying size, that was often seen in the distended vesicle. It is well illustrated in Plate 1.8. Umbilication often persisted into the pustular stage, but as the lesion progressed the fibrinous threads within it were destroyed and its surface usually became flattened because of absorption of fluid (Plates 1.11 and 1.12).

#### *Distribution of the rash*

The rash of smallpox had a characteristic "centrifugal" distribution pattern. This is apparent in the series of full-body photographs of the Pakistani infant (e.g., Plate 1.11), but is better shown in Plate 1.17. The rash was most dense on the face; more dense on the extremities than on the trunk; and, on the extremities, it was more dense on the

distal parts than on the proximal, on the extensor than on the flexor surfaces and on the convexities than on the concavities. The apex of the axilla was relatively free of lesions compared with the folds; this was known as Ricketts' sign. The palms of the hands and the soles of the feet were involved in a majority of cases (Plate 1.16).

On the face, the rash was more profuse on the upper than on the lower half, but in a small proportion of cases it was more uniformly distributed. On the trunk, it was usually denser on the back than on the front, and, on the front, it was more dense on the chest than on the abdomen. On the abdomen, the upper half usually exhibited a more profuse rash than the lower half.

Ricketts (1908) described at length the fine details of the distribution of the rash, which he regarded as a feature of great value in differential diagnosis. Such minute consideration was no longer necessary when laboratory confirmation of a tentative diagnosis became possible. Ricketts also provides several illustrations of the way in which irritation or friction could produce a local concentration of skin lesions. His suggestion that the "centrifugal" distribution of the rash was due to exposure of the face and forearms in habitually clothed persons was not supported by the universal observation of the same characteristic distribution in habitually scantily clothed patients made by workers in several countries during the global smallpox eradication programme.

### Clinical Course

The appearance and evolution of the rash in ordinary-type smallpox have already been described and illustrated. In such cases, the fever, which had fallen somewhat on the 2nd or 3rd day after the onset of the disease, when the rash first appeared, usually rose again by the 7th or 8th day and continued to remain high throughout the vesicular and pustular stages, until scabs had formed over all the lesions (see Fig. 1.1).

If secondary pyogenic infection of the skin occurred, the fever usually remained elevated. Respiratory complications, which sometimes developed on about the 8th day of the disease, were either viral or bacterial in origin. In fatal cases, death occurred between the 10th and 16th days of the illness. Among survivors, scabs separated by the 22nd–27th days, but “seeds” in the palms and soles remained much longer unless artificially removed.

### Grades of Severity

As has been pointed out earlier, so many cases of variola major belonged to the ordinary type, covering a wide range of severity, that some subdivision that was related to prognosis was found useful. That commonly employed related to the extent of the rash, and the terms “confluent”, “semiconfluent” and “discrete” were used by Rao (1972) and others. However, it is important to point out that such grades were part of a continuous spectrum; the numbers of pustules in individual cases could vary from a few to several thousand.

#### *Confluent ordinary-type smallpox*

This subtype encompassed cases in which the pustular skin lesions on the extensor surfaces of the extremities as well as those on the face were confluent (Plate 1.18). In such cases the temperature, which had fallen on the 4th or 5th day after the onset, rose again 2 days later and remained elevated until scabbing was complete. Sometimes the toxæmia did not abate and the temperature did not fall even after scabs had formed over all lesions; when this occurred the prognosis was poor. In Rao's series the case-fatality rate of confluent ordinary-type smallpox in unvaccinated subjects was 62%.

#### *Semiconfluent ordinary-type smallpox*

This was distinguished from confluent ordinary-type smallpox by an arbitrary criterion: the rash was confluent on the face but discrete on the body, including the forearms. A secondary fever often developed during the pustular stage, but the temperature and toxæmia were less marked than in the confluent subtype and the temperature subsided as soon as the scabbing had started. In Rao's series the case-fatality rate in unvaccinated subjects was 37%.

#### *Discrete ordinary-type smallpox*

This was the commonest clinical type in variola major (42% of cases in unvaccinated subjects and 58% of those in vaccinated subjects in Rao's series). Plates 1.11 and 1.17 illustrate such cases. The lesions were fewer in number and discrete (i.e., separated by normal skin) on the face and elsewhere. In some cases, although the lesions were less numerous, the course of the disease was the same as in the other two subtypes; sometimes there was no secondary fever during the pustular stage. The overall case-fatality rate was much lower than in confluent or semiconfluent ordinary-type smallpox—about 9% in unvaccinated subjects in Rao's series.

### MODIFIED-TYPE SMALLPOX

In 1908 Ricketts wrote:

“By the use of the terms ‘modified smallpox’ and ‘abortive lesions’, no assumption is made as to the state of the patient with regard to vaccination. All that is implied is that he exhibits lesions which, in certain particulars, differ from the type most common among unvaccinated patients. The papules, instead of developing into the large vesicles and pustules of natural smallpox, are transformed into lesions which are generally smaller and often of a different conformation, which do not form pustules of the usual size or wholly fail to suppurate, and which hasten through their course of evolution more quickly than is natural.”

This was written before variola minor became endemic in Great Britain. In reviewing data on 13686 cases of variola minor, Marsden (1936) suggested that:

“... the end results of the action of any of the factors which produce modification are indistinguishable in the individual patient... for example, ‘variola major’ in a vaccinated subject, or in a

**Plate I.16.** **A:** Lesions on the sole of the foot on the 14th day of rash. **B and C:** Palm of the hand and sole of the foot of a 2-year-old Zairean boy on the 21st day of rash. Elsewhere on the body the scabs had separated; on the palms and soles they remained as dark disc-like scabs ("seeds").

WHO

**Plate 1.17.** Distribution of the rash in smallpox. Dorsal and ventral views of a 3-year-old unvaccinated girl from Zaire, on the 5th day of rash. The case would be classified as mild discrete ordinary-type smallpox. The pustules were characteristically most numerous on the face, arms and legs and rather sparse on the trunk.

**Plate I.18.** Confluent ordinary-type smallpox in an unvaccinated woman in her twenties, on the 9th day of the illness. Pustules were confluent on the face, forearms and legs but discrete on the trunk. (From Stojkovic et al., 1974.)

**Plate I.19.** Modified-type smallpox. **A:** Vaccinated Japanese man aged 42 years, on the 10th day of the illness. Note the varying size of the lesions and their rapid evolution. **B:** Vaccinated Japanese woman aged 19 years. Very mild case. **C:** Adult female, Delhi, India. Note lack of toxaemia and diversity in size of lesions. (**A** and **B** from Uchida, 1955; **C** from Herrlich et al., 1967.)

## INTRODUCTION

As this book went to press, endemic smallpox had been eradicated from Europe and North America for almost half a century and from the populous countries of China and India for some 25 and 10 years respectively. The majority of people—including the majority of physicians—now living have never seen a case of this once-dreaded disease. What was it like? For the physician, what were its clinical features and its complications? What factors influenced the prognosis? What diseases entered into its differential diagnosis? Nowhere is there a better answer to these questions than in the book written by Ricketts and illustrated by Byles over three-quarters of a century ago (Ricketts, 1908).

Since then, however, long series of carefully studied cases of both variola major (Rao, 1972) and variola minor (Marsden, 1936) have been documented, and laboratory investigation has become a powerful tool for

confirmation of the diagnosis in puzzling cases. Further, during the global smallpox eradication programme a large number of WHO epidemiologists and their national counterparts had extensive experience of smallpox as it occurred in the field in urban and rural areas and among nomads, as distinct from the hospitals from which Ricketts's, Rao's and Marsden's material was drawn. However, only limited clinical studies were possible in rural situations, outside of hospitals. The most comprehensive clinical study of variola major in a non-hospital setting is a series of 539 cases seen in their houses in Pakistani Punjab in 1966–1967 (Mack et al., 1970). Where relevant, data from this study will be used to supplement the description of hospital-based cases described by Rao (1972). An attempt has been made to interpret the symptoms in the light of current understanding of the pathogenesis and immunology of orthopoxvirus infections, as outlined in Chapter 3.

The plan of the present chapter follows Ricketts in that the account of the clinical features of smallpox consists mainly of a description of the rash, based on photographs of patients, most of which were prepared during the global smallpox eradication programme. Because smallpox is now extinct, we have to take the unusual step, in the clinical description of a human disease, of referring to it in the past tense; this was previously the case only with diseases that apparently disappeared and could be identified only by contemporary descriptions, such as the "English sweat", or the "sweating sickness".

JOYCE GREEN HOSPITAL, DARTFORD, ENGLAND

**Plate 1.1.** Thomas Frank Ricketts (1865-1918). Medical Superintendent of the Smallpox Hospitals and of the River Ambulance Service of the Metropolitan Asylums Board, London. His book on the clinical features of smallpox was based on the personal examination of many thousands of cases of variola major.

## VARIETIES OF SMALLPOX

From the time it was first recognized as a distinct disease until about the end of the 19th century, smallpox was regarded as a uniformly severe disease, associated with a high case-fatality rate, in every part of the world. Mild cases and even mild outbreaks of smallpox

were occasionally mentioned in the old literature, but they were the exception; nowhere did endemic mild smallpox occur. Smallpox was designated by many names in various languages, but no one saw a need to distinguish different varieties of smallpox, although the existence of different clinical types (see below) was recognized from the time of Thomas Sydenham (1624-1689) in Europe and much earlier in India and China.

The situation changed when Korté (1904) described a very mild smallpox-like disease, with a case-fatality rate of 1% or less in unvaccinated persons, that had occurred in South Africa for several years and was known locally as kaffir-pox, or "amaas", a word of uncertain origin, possibly a corruption of the Dutch word *masels* or *mazelen* (measles) (Dixon, 1962). Subsequently, Chapin (1913, 1926) recognized that a similar mild disease had been occurring in North America since about 1896, and had subsequently been exported from there to South America, Europe and Australia. There was controversy about the relationship of this disease to smallpox until the mid-1950s (Jong, 1956), but virological studies (see Chapter 2) showed that there was no doubt that "amaas" and "alastrim" (from the Portuguese *alastra*, something which "burns like tinder, scatters, spreads from place to place"), as it was called in South America, were indeed mild varieties of smallpox. Although many other names were used, this clinico-epidemiological variety of smallpox has come to be called "variola minor", a designation that led to the use of the term "variola major" for "classical" smallpox.

Recent studies of viral strains recovered from outbreaks of variola minor in various countries have shown that they fall into two groups distinguishable by biological properties, one consisting of strains derived from outbreaks in South America or traceable to an American source (which we shall call "alastrim" virus) and the other comprising most strains from Africa (see Chapter 2).

During the first half of the 20th century all outbreaks of smallpox in Asia and most of those in Africa were due to variola major (with case-fatality rates of 20% or more in the unvaccinated). Variola minor (with case-fatality rates of 1% or less) was endemic in some countries of Europe and of North and South America and, together with variola major, in many parts of Africa. With the more careful study that began after global eradication had been proclaimed as a goal of WHO in

1959, it was recognized that some outbreaks of smallpox in western, central and eastern Africa and in Indonesia were associated with a lower case-fatality rate than classical variola major, in the range of 5–15% instead of over 20%. Some of these lower figures resulted from aggregating all reported cases in places where both varieties of smallpox were endemic (see Chapter 8), but there were other places where this was not the explanation. The clinical picture of smallpox with a case-fatality rate of 5–15% was indistinguishable from that of variola major, both haemorrhagic and flat types of the disease occurring with about the same frequency as in classical smallpox. Preliminary tests suggested that certain laboratory characteristics of some of the strains recovered from these outbreaks were intermediate between those of variola major and variola minor (see Chapter 4), but later studies failed to support the differentiation of a separate "intermedius" virus. In this book all outbreaks of smallpox will be categorized as either variola major, with case-fatality rates of 5–25% and occasionally more, or variola minor, with case-fatality rates of about 1% or less.

### THE CLASSIFICATION OF CLINICAL TYPES OF VARIOLA MAJOR

It has long been recognized that several clinical types of variola major could be distinguished which differed in prognosis, differential diagnosis and transmissibility. The old subdivision according to the density of the focal eruption was shown by Dixon (1962) and Rao (1967) to have less prognostic value than a classification based on the nature and evolution of the rash. For this reason a WHO Scientific Group on Smallpox Eradication (1968) adopted the classification proposed by Rao and fully described in his book on smallpox (Rao, 1972). A WHO Expert Committee on Smallpox Eradication (1972) reaffirmed its acceptance of this classification (Table 1.1), according to which the commonest clinical type (ordinary-type smallpox) is subdivided in relation to the density of the rash, since this had prognostic significance. The great majority of cases of variola major seen in hospitals among both unvaccinated and vaccinated persons—88.8% and 70% respectively in Rao's series of 6942 cases

WHO, 1971

**Plate 1.2.** A. Ramachandra Rao (b. 1917). Formerly Superintendent of the Infectious Diseases Hospital, Madras, India. His book on smallpox was based on the personal study of nearly 7000 hospitalized cases of variola major. He also made important contributions to the understanding of the epidemiology of smallpox in India (see Chapter 15).

**Table 1.1.** A classification of clinical types of variola major<sup>a</sup>

Ordinary type	Raised pustular skin lesions. Three subtypes: confluent—confluent rash on face and forearms; semiconfluent—confluent rash on face, discrete elsewhere; discrete—areas of normal skin between pustules, even on face.
Modified type	Like ordinary type but with an accelerated course.
Variola sine eruptione	Fever without rash caused by variola virus; serological confirmation required.
Flat type	Pustules remained flat; usually confluent or semiconfluent. Usually fatal.
Haemorrhagic type	Widespread haemorrhages in skin and mucous membranes. Two subtypes: early, with purpuric rash; always fatal; late, with haemorrhages into base of pustules; usually fatal.

<sup>a</sup> Based on Rao (1972).

Table 1.2. The frequency and case-fatality rates of different clinical types of variola major, according to vaccination status (presence of a scar) in hospitalized patients in Madras<sup>a</sup>

Clinical type	Unvaccinated subjects			Vaccinated subjects		
	Number of cases	Percentage of total	Case-fatality rate (%)	Number of cases	Percentage of total	Case-fatality rate (%)
Ordinary type:	3 147	88.8	30.2	2 377	70.0	3.2
Confluent	808	22.8	62.0	156	4.6	26.3
Semiconfluent	847	23.9	37.0	237	7.0	8.4
Discrete	1 492	42.1	9.3	1 984	58.4	0.7
Modified type	76	2.1	0	861	25.3	0
Flat type	236	6.7	96.5	45	1.3	66.7
Haemorrhagic type:	85	2.4	96.4	115	3.4	93.9
Early	25	0.7	100.0	47	1.4	100.0
Late	60	1.7	96.8	68	2.0	89.8
Total	3 544	—	35.5	3 398	—	6.3

<sup>a</sup> Based on Rao (1972).

(Table 1.2)—were ordinary-type smallpox (and other reported series confirm this); the case-fatality rates in unvaccinated cases with confluent, semiconfluent and discrete rashes were 62%, 37% and 9.3% respectively. Although its use was suggested by Rao, such a subclassification is hardly justified for modified-type or flat-type cases, but it is useful to consider early and late haemorrhagic-type cases separately, since they were probably the results of different pathophysiological processes.

A special comment is required on the designation of cases as vaccinated by both Rao (1972) and other investigators. Until freeze-dried vaccine became available and regular assessment was made of the results of vaccination, many vaccinations, especially in tropical countries, were performed with vaccine of less than the required potency (see Chapter 11). The categorization of a subject as "vaccinated" was made on the basis of the presence of what was regarded as a vaccination scar. The presence of such a scar was, however, not certain evidence of successful vaccination. The rotary lancet, used for vaccination on the Indian subcontinent, was attended by considerable trauma, and sometimes bacterial infection alone could produce scarring. On the other hand, vaccination by the jet injector sometimes resulted in a very small scar which might be overlooked on the skin of subjects bearing many scars of traumatic origin. In spite of these shortcomings, the vaccination scar provided a more easily determined and reliable index of an individual's immune status *vis-à-vis* smallpox than was possible with other infectious diseases.

## ORDINARY-TYPE SMALLPOX

### The Incubation Period

The incubation period is the interval between the implantation of infectious virus and the onset of the first symptoms, which in smallpox were fever and constitutional disturbances. Determination of the length of the incubation period is discussed in detail in Chapter 4; in exceptional instances the duration, from the time of infection until the onset of fever, was as short as 7 days or as long as 19 days, but in the great majority of cases the period extended over 10–14 days, usually 12 days.

### Symptoms of the Pre-eruptive Stage

The incubation period in smallpox was a period of intense activity in terms of viral replication and spread within the body and the development of the immune response (see Chapter 3), of which there was at that time no clinical evidence. It ended when the patient became feverish and ill (Fig. 1.1). The onset of fever and malaise was sudden, the temperature usually rising to between 38.5 °C and 40.5 °C. Other symptoms varied in frequency (Table 1.3). Patients suffering from variola major usually complained of a splitting headache, sometimes frontal but usually generalized, and many complained of severe backache (Rao, 1972). A small proportion of children had convulsions and some adults were delirious at this stage. Vomiting occurred in about half of all patients, and

Fig. 1.1. The clinical course of moderately severe ordinary-type smallpox in an unvaccinated subject: the temperature chart, the development of rash, the presence of virus in the blood and oropharyngeal secretions and the time of appearance of neutralizing antibody in the serum. (Data from various sources.)

diarrhoea in about 10%. Some suffered abdominal colic, which could lead to a diagnosis of appendicitis. The patient was usually ill, with an appearance of general toxæmia. By the 2nd or 3rd day (rarely the 4th) the temperature had fallen and the patient felt somewhat better; at this time the macular rash appeared.

In older writings (e.g., Ricketts, 1908) there was often reference to the occurrence of an erythematous rash during the pre-eruptive phase (prodromal rash), best seen in fair-

skinned subjects (Plate 1.3A and B). Some authors (Dixon, 1962; Rao, 1972) have cast doubt on its occurrence in unvaccinated subjects, but all agree that a fleeting "allergic" rash sometimes occurred in vaccinated individuals, most readily visible around the vaccination scar (see Plate 1.3), in the axillae, behind the knees and in the inguinal region. The erythematous rash common in the early stages of haemorrhagic-type smallpox had to be distinguished from the prodromal rash of ordinary-type or modified-type smallpox.

Table 1.3. Frequency of symptoms (percentages of cases) in the pre-eruptive stage in variola major and variola minor

Symptom	Variola major <sup>a</sup>	Variola minor <sup>a</sup>	
	6942 cases (Rao, 1972)	12 847 cases (Marsden, 1936)	859 cases (Noble et al., 1970)
Fever	100.0	..	98.2
Headache	90.0	75.0	79.4

### Impressions of Smallpox in Bombay in 1958

"The majority of patients had fully developed smallpox in the suppurative stage, with confluent pustules covering the entire body. The head was usually covered by what appeared to be a single pustule; the nose and the lips were glued together. When the tightly filled vesicles burst, the pus soaked through the bedsheet, became smeared on the blanket and formed thick, yellowish scabs and crusts on the skin. When the pulse was taken tags of skin remained stuck to the fingers... When secondary haemorrhage appeared, the affected area of skin formed a single black mass.

"All the gravely ill patients were also tortured by mucosal symptoms. The tongue was more or less swollen and misshapen and hindered breathing through the mouth. The voice was hoarse and faltering. Swallowing was so painful that the patients refused all nourishment and, in spite of agonizing thirst, often also refused all fluids. We saw patients with deep invasion of the respiratory passages... Wails and groans filled the rooms. The patients were conscious to their last breath.

"Some... just lay there, dull and unresponsive. They no longer shook off the flies which sat on purulent eyelids, on the openings of mouth and nose, and in swarms on the inflamed areas of the skin. But they were still alive, and with touching gestures they lifted their hands and begged for help." (Translated from Herrlich, 1958.)

naturally immune, may be indistinguishable at the bedside, as in the laboratory, from 'variola minor'. Furthermore, it is affirmed that the sole method of determining with certainty the primary factor responsible for modification in the individual patient is continued observation of the character of the disease in other patients infected by him or from a source in common with him; and, similarly, that variola major is to be distinguished from variola minor only by epidemiological study of the course of the outbreak; for the clue is to be sought in the fact that, when the infective agent is of a persistently degraded virulence (variola minor), modification of attack is invariable, because it is independent of the patient's immunity."

Following Rao, a WHO Scientific Group on Smallpox Eradication (1968) defined modified-type smallpox in much the same way as had Ricketts:

"In this clinical type, which occurs mostly in vaccinated patients, the modification relates to the character and development of the focal eruption; crusting is complete within 10 days. The pre-eruptive illness may be severe and is not necessarily of short duration, but secondary fever during the evolution of the eruption is usually absent. The skin lesions tend to evolve more quickly, are more superficial, and may not show the uniformity characteristic of the more typical smallpox eruption. The lesions are often few in number, but even when they are numerous they show some pleomorphism and evolve rapidly."

A WHO Expert Committee on Smallpox Eradication (1972) qualified this description

by relating modified-type smallpox specifically to smallpox in vaccinated persons.

When preparing this book, we debated this aspect of the definition at some length and eventually agreed to adhere to the older convention—namely, that the term "modified type" connoted smallpox that was accelerated in its clinical course, compared with the expected evolution of ordinary-type variola major, rather than smallpox whose course was modified by vaccination. By far the commonest reason for an accelerated course in variola major was vaccination some years earlier (Plate 1.19), although Mack et al. (1970), who did not categorize any cases as modified-type smallpox, noted that in their series the rapidity of maturation was not associated with either vaccination status or lesion density. In Rao's series, 25% of the cases in vaccinated subjects were classed as modified type, but only 2% of those occurring in unvaccinated subjects were so categorized. No fatal cases occurred in modified-type smallpox. Plate 1.20 illustrates the way in which even confluent lesions could progress much more rapidly than usual. However, modified-type smallpox was usually manifested by fewer lesions as well as by an accelerated clinical course.

### VARIOLA SINE ERUPTIONE

Febrile illness sometimes occurred among vaccinated contacts of cases of smallpox, with

**Plate 1.20.** Confluent modified-type smallpox in a vaccinated adult male. **A:** In the papular stage but profuse. **B:** Early vesicles were confluent and suggested a severe attack, but although the face became swollen (**C**) the lesions did not increase in size and many became prematurely pus-capped. **D:** At a stage when the confluent rash of ordinary-type smallpox would have been approaching its maturity, the lesions had become encrusted and the swelling of the features had subsided. Individual lesions were small, with fleshy deep-seated bases. (From Ricketts, 1908.)

a sudden onset, a temperature of about 39 °C, headache and sometimes backache. Within 48 hours or often less the attack had subsided and the temperature was normal. Without laboratory tests it was impossible to determine whether these symptoms had been due to infection with variola virus, but the finding of high complement-fixing antibody in such patients (see Chapter 3), or a rise in antibody

titres between the first and second bleeds, indicated that the fever had indeed been due to infection with variola virus; such cases have been called variola sine eruptione (Table 1.4).

Occasionally viral isolations have been made from oropharyngeal swabs or washings from such patients. Marennikova et al. (1963) mention one such case; virus was recovered

Table 1.4. Serological evidence for variola sine eruptione in contacts of cases of smallpox<sup>a</sup>

### Contact Fever

"Variola major was introduced into Durban from India in 1943 and spread widely in South Africa. I was personally involved with one of the patients admitted to Baragwanath Hospital. The physician-in-charge phoned to say that a patient had developed a profuse rash which he felt was probably due to a virus infection. One look at the patient convinced me that she had virulent confluent smallpox. The patient coughed in my face as I was examining her. In spite of having been revaccinated many times, indeed each time I saw a patient with smallpox and again on this occasion and each time responding with an immune reaction, I developed a high fever 12 days later, beginning with chills, muscle pain, especially in the small of the back, and headache and photophobia. My throat became sore and intensely itchy and a white membrane formed on the tonsils and pharynx, presumably an outward sign of an immune reaction taking place at the virus-blood junction. Also of interest was a marked erythematous reaction which developed at the site of the inoculation of the vaccine, presumably an immunological reaction against the antigen deposited at the site in the skin. This reaction became apparent at the time of defervescence. At the same time two vesicles, one on my ankle and one on my wrist, appeared and went through the typical stages of vesicle, pustule and scab.

"My infection seems to have been a case of 'contact fever', a condition which had been recognized as occurring in fully vaccinated individuals many years ago. One of the sisters and the physician attending this patient developed a similar illness also, in spite of revaccination immediately the diagnosis was made." (J. H. S. Gear, personal communication, 1983.)

from pharyngeal swabs obtained on the 3rd day of illness from a patient who did not get a rash. Subsequently, Shelukhina et al. (1973) reported the isolation of variola virus from the throat swab of a recently vaccinated child who had been in close contact with a case of smallpox and who was feverish when the specimen was taken, but who did not develop a rash. Verlinde & Tongeren (1952) reported positive results in 2 out of 13 contacts of cases of variola major from whom pharyngeal washings were taken. One of them was a vaccinated woman from whom virus was recovered on the 14th day after contact, at a time when she had fever and constitutional symptoms. No rash developed. The other person apparently had a subclinical infection (see below).

Sometimes conjunctivitis was the only clinical manifestation of smallpox infection. Dekking et al. (1967) recovered variola virus from the tear fluid of 7 women, all thought to have had smallpox in infancy, who had signs of conjunctivitis after nursing children who died of smallpox. In a study directed at the possibility of conjunctival infection in smallpox contacts, Kempe et al. (1969) reported that conjunctivitis but no other illness developed in 21 out of 55 close family contacts of smallpox patients. Variola virus was recovered from the conjunctival exudate of 12 of them. Four of these 12 patients on whom serological tests were carried out showed antibody rises compatible with recent smallpox.

Medical attendants who had been vaccinated and revaccinated but had not often been exposed to smallpox cases sometimes suffered from what appeared to be an allergic pneumonitis ("smallpox-handler's lung"). Fever, constitutional symptoms and signs of pneumonia developed between 9 and 18 days after exposure to cases of smallpox, and X-rays showed diffuse mottling of the lungs (Howat & Arnott, 1944; Leroux et al., 1955; Evans & Foreman, 1963). None developed a rash, and attempts to recover variola virus from throat washings were unsuccessful.

### **SUBCLINICAL INFECTION WITH VARIOLA MAJOR VIRUS**

There was no easy distinction between variola sine eruptione and subclinical infection, especially among persons living in

circumstances in which malaria was endemic and feverish illnesses, from that or other causes, were so common as to be taken for granted.

### **Evidence from Viral Isolations**

Only a few virological studies of smallpox contacts have been carried out (see above and Chapters 3 and 4). Variola virus was occasionally recovered from the throat swabs of such subjects, sometimes for several days in succession, but most of them had been vaccinated and never developed symptoms. Their infections would thus have to be classified as subclinical.

### **Evidence from Serological Studies**

Serological diagnosis of past infection with variola virus depended on the fact that certain serological tests, such as the complement-fixation test, gave positive results (with high titres) for relatively short periods while others remained positive for a prolonged period, both after vaccination and after overt smallpox (Chapter 3).

Heiner et al. (1971a) carried out a detailed study of subclinical infection in villages and individual houses in West Pakistan in 1968-1969, in which overt smallpox had occurred in 68.8% of the unvaccinated and 3.2% of the vaccinated household or compound contacts. Retrospective positive serological diagnoses probably included some cases of smallpox with very few lesions and variola sine eruptione (misdiagnosed or ignored) as well as truly subclinical infections, but the figures obtained give an indication of the frequency of unrecognized smallpox as it occurred in endemic regions.

Two groups of people were studied. "Healthy contacts" were individuals who had not contracted overt smallpox, but had been household or compound contacts of a recent case of smallpox, and had not been vaccinated within 9 months of the study. The principal control group (Group 1 of Table 1.5) consisted of similar subjects who lived in the same villages but had not been in such close contact with smallpox cases. Two subsidiary control groups were used to determine the persistence of antibodies after vaccination; members of one group (Group 2 of Table 1.5) had been vaccinated annually but not within 9 months

Table 1.5. Comparison of titres of complement-fixing and haemagglutinin-inhibiting antibodies among vaccinated close contacts of cases of variola major and vaccinated controls<sup>a</sup>

	Number of close contacts	Number of controls <sup>b</sup>		
		Group 1	Group 2	Group 3
Complement fixation:	143	62	37	40
Geometric mean	38.6	< 10	< 10	< 10
% of sera $\geq 1/40$	54.5	6.5	8.1	10.0
Haemagglutination inhibition:				
Geometric mean	10.5	< 4	4.2	5.8
% of sera $\geq 1/16$	49.0	11.3	13.5	22.5

<sup>a</sup> Based on Heiner et al. (1971a).<sup>b</sup> Group 1: village contacts; Group 2: vaccinated annually; Group 3: vaccinated 5 years or more before study.

of the study, and members of the other group (Group 3 of Table 1.5) had last been vaccinated 5 years or more before the study. The highly significant differences between the close contacts and controls revealed by these tests were supported by similar results using other serological tests (neutralization, passive haemagglutination-inhibition and immunodiffusion). The frequency distribution of positive titres among the controls was unimodal, the majority being negative or having very low titres (Fig. 1.2). The titres of the contact group had a bimodal distribution, about half being negative or very low and the other half positive. This serological evidence indicates that subclinical infection that was accompanied by enough replication of virus to stimulate the production of complement-fixing and haemagglutinin-inhibiting antibodies occurred in many of the vaccinated close contacts of cases of variola major. Rao et al. (1970) came to a similar conclusion, using a gel-precipitation test with both variola and

vaccinia antigens. There was also suggestive but inconclusive evidence that inapparent infection occurred among subjects who had recovered from smallpox years before, a result that has parallels in measles (Ueda et al., 1969).

### FLAT-TYPE SMALLPOX

Flat-type smallpox was so called because the lesions remained more or less flush with the skin at the time when raised vesicles formed in ordinary-type smallpox (Plate 1.21). This manifestation of the disease was seldom encountered (6.7% of cases in unvaccinated subjects in Rao's series), and the majority of cases (72%) occurred in children. It was very rare in successfully vaccinated subjects. The prognosis was always grave and most cases were fatal (see Table 1.2).

The pre-eruptive stage lasted 3-4 days, with the usual constitutional symptoms, which were severe and continued after the appearance of the rash. The fever remained elevated throughout and the patient had severe toxæmic symptoms.

### The Rash

The enanthem on the tongue and palate was usually extensive and sometimes confluent. Occasionally a severe enanthem occurred on the rectal mucous membrane. The characteristic feature of flat-type smallpox was the nature of the skin lesions. Unlike the regular evolution seen in ordinary-type smallpox, the focal lesions in the skin matured very slowly, and at the papulovesicular stage, about 6 days after the onset of fever, a small depression was visible. By the 7th or 8th day the lesions were flat and appeared to be buried in the skin (Plate 1.21). Most lesions had haemorrhages

Fig. 1.2. Distribution of titres of complement-fixing antibodies to variola antigens in contacts and controls, as defined in text. (Data from Heiner et al., 1971a.)

into their base, the central flattened portions appeared black or dark purple, and they were surrounded by an erythematous areola. The lesions differed from those of ordinary-type smallpox in that the vesicles contained very little fluid, they were not multilocular, and they did not show umbilication. In contrast to the "shotty" feel of the lesions in ordinary-type smallpox, they were soft and velvety to the touch. No further evolution of the lesions occurred and frank pustules were rarely seen, although occasionally a few lesions, especially on the dorsum of the feet and hands, became pustular, while elsewhere on the body they remained as flat vesicles. Because of their superficial nature, the skin over the lesions peeled off after slight trauma, sometimes leaving extensive raw areas. Often the skin lesions did not conform to the classical "centrifugal" distribution.

### Clinical Course

Throughout the course of the disease the patient was toxic and febrile. Respiratory complications, including oedema of the lung and sometimes frank pneumonia, set in by the 7th or the 8th day after the onset of fever. Rao noted that unvaccinated children sometimes developed an acute dilatation of the stomach 24-48 hours before death, which usually occurred between the 8th and the 12th day. A day or two before death, the colour of the lesions changed to an ashen grey, which, along with acute dilatation of the stomach, was a bad prognostic sign. In cases with a confluent enanthem on the tongue and palate, the mucous membrane sloughed, leaving large raw areas. Some patients passed blood and mucus in the early stages of the disease, indicating the extensive involvement of the rectal mucous membrane, and in such cases, just before death, the rectal mucous membrane was sometimes sloughed off.

Among the few who survived, scabbing usually began on about the 13th-16th day after the onset of fever and was complete by about the 21st day. The scabs were thin and superficial and separated rapidly, leaving very superficial scars. Because of the bleeding into the base of the lesions, the scabs, before they dried, were purplish in colour.

Flat-type smallpox was probably due to the infection of particularly susceptible subjects with virulent strains of variola virus; it never occurred in variola minor. The appearance of

the lesions suggested a deficient cellular immune response in these patients, but no relevant studies were ever reported.

## HAEMORRHAGIC-TYPE SMALLPOX

### General Features

Considering its comparative rarity (only 200 cases in Rao's series of 6942 hospitalized patients in Madras), a great deal has been written about haemorrhagic-type smallpox. No doubt this preoccupation was partly due to the rarity of the syndrome, its great severity and the difficult problem that it presented in differential diagnosis. This was particularly true in countries in which smallpox was no longer endemic; there were many instances in which outbreaks or their extension could be traced to an unrecognized importation of haemorrhagic-type smallpox (see, for example, Benn, 1963; Stojkovic et al., 1974).

Histopathological studies (Bras, 1952a) support the clinical distinction of two varieties of haemorrhagic-type smallpox—what Curschmann (1875) and Immermann (1895) called "purpura variolosa" and "variola pustulosa haemorrhagica." We shall follow Rao (1972) in calling them early and late haemorrhagic-type smallpox respectively. Early haemorrhagic-type smallpox was characterized by haemorrhages into the skin and/or mucous membranes early in the course of the illness. Subconjunctival haemorrhages were the most common, and bleeding from the gums, epistaxis, haematemesis, haemoptysis, haematuria, as well as vaginal bleeding in women, occurred at any time in the course of the illness.

In late haemorrhagic-type smallpox haemorrhages into the skin and mucous membranes often occurred, and usually also into the bases of the developing skin lesions. Some of these cases could equally well have been considered as cases of flat-type or confluent ordinary-type smallpox, associated with haemorrhages as a complication. However, all classifications contain an arbitrary element.

Haemorrhagic-type smallpox, of both subtypes, had two unusual epidemiological features: it occurred mostly in adults (Calcutta: Guha Mazumder et al., 1975; Madras: Rao, 1972) and in some extensive series (the Calcutta and Madras series) it was as common in vaccinated as in unvaccinated subjects (see

**Plate 1.21.** Flat-type smallpox. **A:** Adult Indian man. **B** and **C:** Unvaccinated young woman from Madras, India, on the 6th day of rash; she died 3 days later. Note severe toxæmia and extensive flat pustules in both cases. (**A** from Herrlich et al., 1967.)

**Plate I.22.** Early haemorrhagic-type smallpox. **A:** In an unvaccinated 60-year-old woman, who died on the 4th day of illness. Besides the rash illustrated she bled from many other sites, with subconjunctival haemorrhages, a bloody enanthem, epistaxis, haematuria, blood in the faeces and metrorrhagia. **B:** Subconjunctival haemorrhage. **C:** Fully developed haemorrhagic diathesis and death. (**A** from Stojkovic et al., 1974; **B** and **C** from Herrlich et al., 1967.)

**Plate I.23.** Contrast between early and late haemorrhagic-type smallpox. **A and B:** Early haemorrhagic-type smallpox in a pregnant 18-year-old woman, showing severe toxæmia, petechial exanthem and bleeding from body openings; 1 hour before death. **C:** Late haemorrhagic-type smallpox in young woman, showing bleeding in base of pustules and development of a general haemorrhagic diathesis late in the disease. (From Herrlich et al., 1967.)

**Plate I.24.** Variola minor in a 30-year-old unvaccinated Somali woman, 12 days after the onset of rash. The patient was not very sick and was ambulant throughout the disease. The lesions on the face were sparse (**A**) and evolved more rapidly than those on the arms and legs (**B** and **C**).

Table 1.2). On the other hand, Sarkar et al. (1972), in a series of 170 cases observed in Calcutta during the years 1963–1969, recorded no cases of haemorrhagic-type smallpox among 81 patients who had been vaccinated but did note 32 cases among 89 unvaccinated subjects.

### Early Haemorrhagic-Type Smallpox

With minor changes, descriptions of early and late haemorrhagic-type smallpox, and statistical data relating to them, are taken from Rao (1972). There is no point in trying to distinguish a "pre-eruptive" stage in this subtype, since death usually occurred before the focal rash had time to develop. The onset was sudden and the high fever was accompanied by severe headache and backache which often persisted until the patient died. Patients looked very sick and were restless, anxious and pale. On the 2nd day of fever the whole body was suffused with a generalized erythema, and petechiae and areas of ecchymosis appeared (Plate 1.22A and C). Subconjunctival haemorrhage was the most common (Plate 1.22B), but haemorrhages occurred from many sites (Table 1.6). On the 3rd day of the disease, the whole skin exhibited a finely textured matted surface and was velvety to the touch (Plate 1.23A and B), and 24 hours later it resembled dark-purple velvet, a feature seen most clearly in fair-skinned patients.

Patients showed signs of severe toxæmia, and became restless, breathless, and complained of heaviness and pain in the chest. Ricketts (1908) described and illustrated a characteristic expression of the face, with the

features immobile, the lines of expression obliterated, the cheeks relaxed, the lips full and parted and the eyelids drooping—an expression of profound prostration. He also spoke of a fetid odour of the breath that was common to the toxæmic state in most cases of very severe smallpox, whether they were haemorrhagic, flat or confluent ordinary in type. Death occurred rather suddenly on about the 6th day of fever, patients usually remaining conscious until the end. Clinical observation and postmortem studies (Bras, 1952a) revealed that these patients did not die of haemorrhage, but they showed evidence of heart failure and sometimes oedema of the lungs. If the patient survived a few days longer, the superficial layers of the skin became raised and fluid collected underneath, forming large blebs containing serous or sero-sanguinous fluid, which ruptured after slight trauma, leaving extensive raw areas.

As was true for haemorrhagic-type smallpox in general, the early haemorrhagic subtype was more common in adults, 88% of all cases in Rao's series being in persons over 14 years of age. Two-thirds of his cases were in women, pregnant women being especially susceptible. Of all the smallpox cases occurring in pregnant women in the Madras series, 16% were of this subtype, compared with only 0.9% among non-pregnant females and 0.8% among males in the age group 15–44 years. If a vaccinated person contracted haemorrhagic-type smallpox the outcome was not influenced by the prior vaccination; indeed, Rao (1972) states that a few cases of fatal early haemorrhagic-type smallpox occurred even among persons who had recently been successfully revaccinated.

Table 1.6. Frequency of haemorrhages (percentages of cases) in different anatomical sites in early and late haemorrhagic-type smallpox<sup>a</sup>

Site or symptom	Early haemorrhagic type (72 cases)	Late haemorrhagic type (128 cases)
Skin	85	16
Conjunctiva	65	52
Haematuria	25	29
Gums	20	29
Haemoptysis	12	30
Melaena	10	8
Epistaxis	2	3
Haematemesis	1	4
Vagina (women only)	90	58

<sup>a</sup> Based on Rao (1972).

### Late Haemorrhagic-Type Smallpox

This form was differentiated from early haemorrhagic-type smallpox by the occurrence of haemorrhages after the appearance of the rash. The pre-eruptive stage lasted for 3-4 days, the temperature being about 40 °C, with severe toxæmic symptoms like those described for early haemorrhagic-type smallpox, which continued unabated even after the appearance of the rash. The lesions, which started as macules, soon became papules but thereafter matured very slowly. They sometimes showed haemorrhages into their bases, which gave them a "flat" appearance (Plate 1.23C). Bras (1952a) noted that sections of such lesions showed that often the bleeding actually occurred in the corium beneath the pustules rather than in the pustules themselves.

Bleeding occurred in various mucous membranes, although somewhat less frequently than in early haemorrhagic-type smallpox (Table 1.6). If the haemorrhagic focal lesions were "flat", they did not evolve beyond the vesicular stage but then flattened out and became black. In about 15% of Rao's cases they matured into pustules, which followed the same course as in ordinary-type smallpox. In these cases there were no haemorrhages into the lesions, but only into mucous membranes.

The majority of cases of late haemorrhagic-type smallpox were fatal (see Table 1.2), death occurring between the 8th and the 10th day. Cases with flat lesions had a higher fatality rate than those with raised pustular lesions. Among the patients who survived, the haemorrhages gradually resolved during a prolonged convalescence. However, in the few survivors among cases with the flat type of lesions, scabs usually formed sooner, resulting in only superficial scarring.

Of cases in the Madras series, 80% occurred in persons over 14 years old. Unlike the situation with early haemorrhagic-type smallpox, there was little difference in frequency between men and women, although pregnant women were slightly more susceptible. In Rao's series, of all pregnant women with smallpox, 6% had the late haemorrhagic type, compared with 2% of non-pregnant females and 2.1% of males in the age group 15-44 years. As with early haemorrhagic-type smallpox, Rao observed cases among persons who had apparently been successfully vaccinated, not only in infancy but also at later ages.

Haemorrhagic-type smallpox was primarily due to defects in the response to infection by individual patients. It was very rare in variola minor (see below), but epidemiological evidence suggested that viral strains of unusual virulence were not the main cause of haemorrhagic-type smallpox. For example, Rao (1972) noted that there had not been a single haemorrhagic-type case among the contacts of 385 cases of haemorrhagic-type smallpox in Madras, although many of these contacts had contracted other forms of smallpox; this was an even longer series than that analysed in Table 1.2. Postmortem studies (Bras, 1952a) excluded concomitant bacterial infection as a precipitating factor. As will be shown in a later section, these cases were characterized by high and sustained viraemia, severe depletion of platelets and a poorly developed humoral immune response.

### VARIOLA MINOR

This variety of smallpox differed greatly from variola major in its spectrum of severity and in its case-fatality rates—about 1% compared with about 20%.

#### Clinical Course

The most comprehensive account of the symptomatology of this disease was provided by Marsden (1936). His observations were based on 13686 cases (most of which he examined personally) that occurred in London between 1928 and 1934. The description which follows is drawn largely from that source, supplemented by the accounts of MacCallum & Moody (1921), Jong (1956) and Noble et al. (1970), and the extensive field experience of epidemiologists working in Brazil, Ethiopia and Somalia during the smallpox eradication programmes in those countries.

Almost all cases of variola minor would have been classified as discrete ordinary- or modified-type smallpox, but in any individual case it was impossible to determine whether the disease was variola major or variola minor. The diagnosis depended on the assessment of the clinical severity of the outbreak; if there were no deaths or only one among 50 or so patients the disease was usually variola minor. Data on the pre-eruptive stage were provided by Marsden, who saw only about 1% of his cases at this stage, and MacCallum & Moody

JOYCE GREEN HOSPITAL, DARTFORD, ENGLAND

**Plate 1.25.** James Pickford Marsden (1900-1977). Formerly Deputy Medical Superintendent, River Hospitals (London County Council), Dartford, Kent, England. He described a series of 13 686 cases of variola minor in outbreaks in London between 1928 and 1934.

(1921), who saw many of the 2333 cases in their Jamaican series during the early stages of the disease. The onset was sudden, with a fever of 40 °C, severe headache and backache and sometimes vomiting. Marsden recorded the occurrence of pre-eruptive rashes in 48 of the cases he saw during this stage; there were typical erythematous prodromal rashes in 37 cases. MacCallum & Moody recorded no such rashes in their mainly dark-skinned patients. The constitutional symptoms of the established disease were usually much less severe than those in cases of variola major with a comparable rash (Plate 1.24). The toxæmia so evident in variola major rarely occurred, and patients with extensive skin rashes were often ambulant. The individual lesions were smaller than those of variola major, so that Marsden was able to count more than 500

lesions on the faces of 295 of his patients without these producing confluence, as would have been expected in variola major. Both MacCallum & Moody and Jong noted that the early vesicles and early pustules were unilocular and were not umbilicated, a clinical finding that was supported by histological examination of biopsy material. The sequence of appearance, the distribution and the nature of the skin lesions were similar to those described earlier for variola major, but their evolution was often more rapid. The eruption became vesicular on the 3rd day after the appearance of the first papules, and within 24 hours had become pustular. Early crusting was established on the 6th or 7th day of rash.

Cases of variola minor could not be classified according to Rao's scheme (see Table 1.1) because of the smaller size and more rapid evolution of the skin lesions. Indeed, the vast majority would have been classified as "modified-type smallpox", which would clearly be a misnomer. Marsden grouped his cases according to the criteria formulated by Ricketts (1893) (Table 1.7). He noted that many of those classified as "discrete" would have been confluent in variola major; none was described as flat-type smallpox.

In keeping with the reduced severity and the more rapid evolution of the rash, secondary fever was rare, occurring in most of the more severe cases but, in Marsden's experience, in only 0.13% of those with fewer than 100 lesions on the face, a group which included 87% of the cases in his series. Both MacCallum & Moody and Jong noted the absence in variola minor of the characteristic fetid odour of variola major.

Haemorrhagic-type cases did occur in variola minor, but they were extremely rare. Marsden recorded 3 cases, one of which recovered; Tigre et al. (1973) describe a fatal case in a 4-year-old boy infected in Argentina in 1970 and refer to 4 others observed in Brazil; Rodrigues-da-Silva et al. (1963) recorded 1 case which survived, and Moody (1922) recorded 2 fatal cases, both in pregnant

women, among 2912 cases of variola minor in an epidemic in Jamaica in 1920-1921.

There were 150 pregnant women in Marsden's series but he commented only on the effects on the fetus, described below, and not on the severity of disease in the mother. The mortality in the Jamaica outbreak described by MacCallum & Moody (1921) was 0.4%, but of the 5 women who died 4 were 6 or 7 months pregnant and all of them displayed a "marked tendency to haemorrhage".

### Variola Sine Eruptione and Subclinical Infection

In a susceptible population the host resistance to any infection has a Gaussian distribution. The data on variola major (see Table 1.2) suggest that there would be few cases of variola sine eruptione and subclinical infection in unvaccinated persons exposed to this infection; however, many more such cases might be expected to occur in variola minor (Table 1.7). Data on the occurrence of such infections are difficult to find, but observations made in Brazil during the 1960s support this view. Positive titres of complement-fixing antibody were found in 6 asymptomatic contacts of children with overt variola minor; most of the contacts had not been vaccinated more recently than 20 years before (Rodrigues-da-Silva et al., 1963). In a carefully studied ward outbreak, Salles-Gomes et al. (1965) observed positive complement-fixing and sometimes haemagglutinin-inhibiting antibody responses among 13 contacts exposed to overt variola minor. Four of these cases occurred in previously fully susceptible patients who had never had variola or been vaccinated.

## SMALLPOX ACQUIRED BY UNUSUAL ROUTES OF INFECTION

### Inoculation Variola and Variolation

Under unusual conditions, smallpox could be accidentally acquired through inoculation. Such cases sometimes occurred among nursing mothers and among those engaged in postmortem work (Lyons & Dixon, 1953), and cutaneous infections were recorded in an outbreak among lace-workers (Boobyer, 1894). Marsden (1936) recorded 50 cases of accidental smallpox inoculation in variola minor and noted that the lesions of inocula-

tion were usually recognized by their larger size and more advanced development than the other elements of the focal rash.

Much more common, however, was the practice of deliberately inoculating variola virus into the skin, practised since ancient times in Africa and India and in China (where, however, infection was usually produced by nasal insufflation) and on a large scale in some parts of Europe and North America during the 18th century (see Chapter 6). Variolation continued to be practised in many parts of Africa and in Afghanistan and Pakistan until quite recent times, and the spread from variolated individuals was an important source of smallpox in Afghanistan and Ethiopia up to the time of eradication in 1973 and 1976 respectively.

The technique of cutaneous variolation has varied at different times and in different places. Detailed descriptions of the methods used during the 18th century in France and other countries of Europe and in North America can be found in Miller (1957) and Razzell (1977b); methods used more recently in Africa and Asia are described in Chapters 14 and 21.

### *Clinical picture*

The clinical picture of inoculation smallpox was influenced by several factors. Inoculation carried out after the manner of modern vaccination produced a local skin lesion that first appeared as a small papule on the 3rd day after the operation. It grew in size and became vesicular by the 5th day, and by the 8th or 9th day there was a large pustular lesion with much surrounding erythema and oedema (see Chapter 6, Plates 6.1-6.3). Fever and constitutional symptoms corresponding to the pre-eruptive stage of ordinary-type smallpox began on the 8th day and often lasted for only 2 or 3 days (Fig. 1.3). There were usually a number of secondary lesions around the primary lesion (see Plates 6.1-6.3), and the generalized rash began on the 9th day on the face, often consisting of very scanty macules, which rapidly became vesicular. Subsequent lesions sometimes appeared over the next 3 or 4 days and evolved more rapidly than in smallpox acquired by the respiratory route. Even in the few cases that had a large number of secondary pustules (which in inoculation smallpox amounted to as many as 300-1000), the lesions matured more rapidly than in

Fig. 1.3. The clinical course of moderately severe ordinary-type variola major in an unvaccinated subject (A); inoculation smallpox (variola) in an unvaccinated subject (B); and primary vaccination (C). (Temperature records from an illustration in Hime (1896) with modified wording.)

ordinary-type smallpox, so that scabbing occurred 3 or 4 days earlier and the lesions, being more superficial, gave rise to less scarring. By the 18th or 19th day most of the scabs, except for the lesions on the palms of the hands and the soles of the feet, had been shed.

Neither haemorrhagic- nor flat-type smallpox seems to have been recorded as a sequel to variola, at least in European and North American practice. This may have been due to the professional interests of the inoculators and their concern to be exempt from any possible blame for deaths that occurred; but, in any event, it was the practice to avoid inoculating especially susceptible persons—pregnant women, children under 2 years of age and the aged and infirm.

Apart from the primary skin lesion, most cases, like those of naturally acquired inoculation smallpox, appeared to fall into the category of modified-type smallpox. Cases with only a primary skin lesion, 1 or 2 days of fever and no rash—variola sine eruptione

were said to be not uncommon. Rao himself suffered from such an infection (Rao, 1972).

Because of the smaller number of lesions and their more rapid maturation, cases of inoculation smallpox were less infectious, and were infectious for shorter periods, than those of smallpox acquired by the respiratory route. Nevertheless, they often did initiate smallpox in unvaccinated (and unvariolated) contacts, both in 18th century practice in Europe and North America and in recent times in Afghanistan and Ethiopia. Such contact cases were no different from those associated with other epidemics due to whatever strain happened to have been used for variolation.

#### Severity

In the hands of some of the famous British practitioners of variolation (e.g., the Suttons—see Razzell, 1977b) the severity of smallpox due to variolation appears to have been low and the mortality less than 2%.

In their day only variola major virus was circulating in Great Britain and some contact cases acquired severe and sometimes fatal smallpox; the explanation for the mild nature of smallpox after variolation lay with the age and health of the inoculated subjects, the route of inoculation and the small dose usually employed.

In Ethiopia, where variolation was practised until 1976, the virus used during the last few decades was variola minor and inoculation smallpox was correspondingly mild; nevertheless, it was an important source of outbreaks during the latter part of the eradication campaign in that country (see Chapter 21).

### Congenital Smallpox

The effects of pregnancy on the clinical course of smallpox in the mother are discussed later in this chapter. Infection of the fetus depended on the growth of the virus in the placenta and its subsequent release into the cord blood. Its frequency was uncertain, since most pregnant women suffering from variola major aborted during the pre-eruptive fever. Occasionally babies born of mothers suffering from smallpox developed symptoms after birth; Rao (1972) records 10 such cases among 116 live births. In these babies, all of whom died, the fever-to-fever interval was 9–12 days. Among the offspring of 84 women who suffered from haemorrhagic-type smallpox (all with intense and sustained viraemia) none of the 21 children born alive developed clinically recognizable congenital smallpox, but 17 of them died in less than 72 hours—too soon for a diagnosis to be made.

The baby was infected in half of 34 pregnancies in which the mother was infected with variola minor during late pregnancy (Marsden & Greenfield, 1934). Usually the infection was acquired *in utero*, at the time of the mother's viraemia; the incubation period then appeared to be 8–9 days, as in inoculation smallpox. If the fetus escaped infection during that time the infant might become infected at birth or later in the neonatal period, especially if the mother's rash was then at an early stage of development. If the mother carried the fetus to term, the newborn infant was usually temporarily immune from smallpox because of maternal antibodies.

Fetal variola was a rare occurrence, reported only in variola minor. In some cases

(MacCallum & Moody, 1921; Ribeiro et al., 1965) the fetus sustained an attack of smallpox *in utero* and was subsequently born alive, having been infected at the time the mother had the disease 2 or 3 months before birth. More often (for example in 8 of the 20 pregnant women in the series described by MacCallum & Moody (1921)) abortion occurred and the macerated fetus was marked with scars from an attack of variola minor sustained *in utero*.

Nowhere in the scientific literature is there a reliable reference to the occurrence of congenital defects caused by smallpox or vaccination in a pregnant woman. Since the usual viral causes of congenital defects are non-cytocidal viruses, whereas variola and vaccinia viruses are both cytocidal, this is not unexpected.

### EFFECTS OF VACCINATION ON THE CLINICAL COURSE OF SMALLPOX

The most important effect of vaccination was the protection of the subject from smallpox, but prior vaccination, even many years before, usually influenced the course of the disease in persons who did show symptoms. The situation in individual subjects depended on a variety of factors, some relating to the host: genetic resistance, physiological state, and interval since vaccination or revaccination; some to the vaccine and its mode of delivery: the strain of vaccinia virus used, the potency of the vaccine and the inoculation procedure employed; and, finally, of course, whether the infection was due to variola major or variola minor virus. Further, it was the general practice to vaccinate or revaccinate contacts; some of these individuals were incubating smallpox at the time of vaccination.

Successful vaccination within 5 years of exposure provided a high level of protection against smallpox. When vaccination had been performed more than 20 years before exposure there was sometimes no residual immunity and the course of the disease was similar to that seen in unvaccinated subjects, although even then the outcome, examined statistically, was modified (Hanna, 1913).

Although its most important effect was the prevention of infection, vaccination also influenced the frequency of different clinical types of smallpox among persons who did contract the disease (see Table 1.2). Not only

was modified-type smallpox much more common among vaccinated patients (25.3% compared with 2.1% in Rao's series), but a larger proportion of ordinary-type cases was classified as discrete (83.5% compared with 47.4%) and flat-type cases were less common (1.3% compared with 6.7%). However, Rao (1972) and Guha Mazumder et al. (1975) reported that, among those who got smallpox, haemorrhagic-type smallpox was slightly more common among vaccinated than among unvaccinated subjects (see Table 1.2 and below). Not all investigators agreed with this view; for example, Sarkar et al. (1972) reported that in a series of 170 cases no cases of haemorrhagic-type smallpox occurred among vaccinated persons, but 32 cases occurred in unvaccinated subjects. Except in modified-type smallpox, which was hardly ever fatal, and haemorrhagic-type, which was almost always fatal, the case-fatality rates were lower in vaccinated than in unvaccinated patients (see Table 1.2).

Vaccination resulted in the modification of three aspects: the toxæmia (and correspondingly the case-fatality rate), the number of lesions, and the character and evolution of the rash. The waning of vaccine protection against these manifestations did not occur uniformly.

### Effects of Vaccination on Toxæmia

The initial constitutional symptoms of smallpox were associated with the replication of variola virus during the incubation period, the end of which was marked by the sudden onset of fever and headache that accompanied the secondary viraemia. In some cases vaccine protection had little apparent effect on symptoms of fever and headache at the end of the incubation period, but no skin lesions developed; the patient was said to have suffered from *variola sine eruptione*, which was occasionally associated with pneumonitis. Sometimes the pre-eruptive stage in vaccinated subjects was accompanied by a fleeting erythematous rash that particularly affected the flexures.

The more toxic forms of smallpox, except for the haemorrhagic type, were much less common in vaccinated than in unvaccinated subjects (see Table 1.2).

### Effects of Vaccination on the Number of Lesions

The skin lesions were initiated by the infection of dermal capillaries by virus released into the circulation during the secondary viraemia (see Chapter 3). Prior vaccination usually reduced the level of viraemia and thus the opportunity for skin lesions to develop; *variola sine eruptione* occurred mainly in vaccinated persons, and confluent lesions were much less common among vaccinated subjects. In Rao's series 16.5% of vaccinated patients who had ordinary-type smallpox were classified as confluent or semi-confluent, compared with 52.6% of unvaccinated patients.

### Effects of Vaccination on the Character and Evolution of the Rash

In some cases of smallpox in vaccinated subjects the character and rate of evolution of the rash differed from the usual pattern, presumably because of the anamnestic response initiated by infection with variola virus in the vaccinated subject. The individual lesions were more superficial and hence did not have the "shotty" feel, and their edges were often irregular. Umbilication and loculation were not found in these superficial lesions, which resembled those of chickenpox. Often the modified lesions were very small, but they could vary quite considerably in size in any particular area of skin (Plate 1.19C). In fair-skinned subjects the red areola around the pustules was often more pronounced—presumably an allergic manifestation. In many vaccinated subjects the rash also evolved more rapidly so that the lesions passed through the stages of macule, vesicle and pustule in 3 or 4 days instead of 7 or 8. On the other hand, many field workers found no such differences in symptomatology, apart from a greater frequency of cases of ordinary-type smallpox with few skin lesions. Smallpox in vaccinated subjects who did contract the disease was no different in other respects from that found in unvaccinated patients. Mack et al. (1970), in cases with similar lesion density, found no differences that could be related to vaccination status in the length of the pre-eruptive stage, the rate of maturation of skin lesions, the occurrence of corneal lesions, the case-fatality rate or the prevalence of residual pockmarks.

### Effects of Vaccination in Variola Minor

In Marsden's series, variola minor occurred in 1756 patients who showed evidence of having been successfully vaccinated, out of a total of 13 686 cases. In only 2 of these was there evidence of vaccination within the previous 5 years and in only 7 within the previous 10 years; the great majority had been vaccinated 20 or more years earlier. In an epidemic in the Netherlands, Jong (1956) found no cases in persons vaccinated less than 30 years before, and, in Brazil, Suzart de Carvalho Filho et al. (1970) found a vaccine-efficacy ratio of 94%, regardless of the interval since previous vaccination (see Chapter 12). Vaccination thus provided very good protection against variola minor, a conclusion which is in keeping with the experience of epidemiologists working in Ethiopia and Somalia during the global smallpox eradication programme.

### LABORATORY FINDINGS

Laboratory observations on cases of smallpox will be described in Chapter 3, as part of an attempt to build up a coherent picture of the pathogenesis of the disease. However, it is useful to examine some of the results here in the context of the symptomatology of smallpox.

#### Virological Observations

The principal value of the laboratory, without which it would have been impossible confidently to certify global smallpox eradication, was the demonstration of the presence or absence of variola virus in vesicle fluid and crusts from suspected cases of smallpox (see below). This section reviews virological findings made on cases of smallpox which may help to explain the clinical signs and symptoms.

#### *Viraemia*

According to the model for the pathogenesis of variola developed in Chapter 3, there was an early transient viraemia soon after infection. The virus then replicated in the lymph nodes, spleen and bone marrow until just before the onset of symptoms, which was associated with secondary viraemia. All the

reported observations of viraemia in smallpox relate to this "secondary" viraemia.

Precise observations were never made on the distribution of variola virions among the various components of the blood (plasma, leukocytes and erythrocytes); by analogy with other poxvirus infections viraemia would have been expected to be primarily cell-associated (see Chapter 3). However, most observations that were made on the blood of smallpox patients utilized either serum or lysed whole blood, the material being inoculated either into monkeys (Kyrle & Morawetz, 1915) or on the chorioallantoic membrane of chick embryos (Downie et al., 1950, 1953, 1969b; Mitra et al., 1966). In haemorrhagic-type smallpox both serum and lysed blood gave positive results; it is possible that viraemia might have been detected more readily in cases of ordinary-type smallpox if separated leukocytes had been examined.

However, the general pattern appears to have been consistent. Although viraemia must always have occurred, virus was only rarely recovered from the blood or serum from cases of ordinary-type smallpox. Downie et al. (1950, 1953) and Mitra et al. (1966) recorded one or two positive results out of many attempts in such cases and then only in the early days of the disease. The picture in haemorrhagic-type smallpox was quite different. Virus was readily recovered from the blood of all cases, the titres were usually high, as determined by titration on the chorioallantoic membrane of chick embryos (Downie et al., 1953, 1969b; Mitra et al., 1966; Sarkar et al., 1969), and viraemia usually persisted until the patient died. Downie et al. (1969b) noted that viraemia was consistently much higher in cases of early than of late haemorrhagic-type smallpox. Patients with haemorrhagic-type smallpox usually also had soluble antigens in their bloodstream (antigenaemia), the level of which was roughly correlated with the level of the viraemia. Although few opportunities occurred for its practical use, the demonstration of antigen in the serum provided a useful and rapid laboratory diagnostic test for haemorrhagic-type smallpox, a disease in which the differential diagnosis was extremely difficult, especially in non-endemic countries, in which it would rarely have been suspected.

Thus haemorrhagic-type smallpox appears to have been associated with overwhelming infection and the continued release of virus from infected cells into the bloodstream; in

other cases demonstrable viraemia was usually restricted to the pre-eruptive and early eruptive stages of the disease.

### *Skin*

Variola virus could be readily demonstrated in the skin lesions of all cases of smallpox, from the earliest stages of the rash until the scabs separated. The large amount of virus in the vesicle fluid was eventually included within the scabs. However, because virus in the scabs was associated with large flakes of inspissated material it appeared to be relatively unimportant as a source of infectivity for contacts, compared with virus in the oropharyngeal secretions (see Chapter 4). In spite of the absence of vesicles or pustules, the skin of cases of haemorrhagic-type smallpox contained very large numbers of virions.

### *Oral and pharyngeal mucous membranes*

The earliest focal lesions in smallpox occurred in the oropharynx, and instead of forming papules and vesicles, as in the skin, these lesions soon ulcerated and thus liberated large amounts of virus into the saliva. This was the major source of infectious virus as far as the transmission of smallpox was concerned (see Chapter 4).

### *Conjunctiva*

Patients with smallpox sometimes had conjunctivitis. Virus could be readily recovered from the conjunctival swabs of patients in whom conjunctivitis developed early in the course of the disease, but usually not from convalescent patients who developed conjunctivitis (Dekking et al., 1967; Kempe et al., 1969; Sarkar et al., 1973a). The occasional appearance of variolous conjunctivitis at or before the onset of fever suggested to Kempe et al. (1969) that the conjunctiva may have been the portal of entry in these cases.

### *Urine*

The interpretation of the results of testing urine for virus was difficult, since patients often had pustules on the skin near the urethral orifice, and catheterization, had it been possible to do this aseptically, was not ethically justifiable. However, viruria was recorded by all investigators who tested the urine from cases of variola major. Positive

results were recorded by Downie et al. (1965a) in 17 out of 34 specimens, and by Sarkar et al. (1973a) in 21 out of 39. The viruria was greater in degree and more persistent in severe cases (haemorrhagic-type smallpox and those with a confluent rash) than in milder cases. No virus was detected in the urine of some cases whose severity was comparable to that of cases with viruria.

## Serological Observations

The immune response in generalized orthopoxvirus infections (including smallpox) is described in Chapter 3; this section summarizes information on the correlation between various serological responses and the clinical severity of smallpox, to the extent that such information is available. Unfortunately, there is an almost complete lack of data on cell-mediated immunity in smallpox, an immune response that was probably of critical importance in the pathogenesis and immunopathology of the disease.

The most comprehensive studies on the serological responses in cases of smallpox are those reported by Downie et al. (1969a,b) on ordinary-type and haemorrhagic-type smallpox, using haemagglutination-inhibition, complement-fixation, gel-precipitation and neutralization tests. In most cases of non-fatal ordinary-type smallpox, antibody was detected by haemagglutination-inhibition and neutralization tests between the 6th and 8th days after the onset; by complement fixation and gel precipitation about 2 days later (Fig. 1.4). The antibody response was slower and

Fig. 1.4. Percentages of positive antibody titres obtained at various times after the onset of ordinary-type variola major, by 4 types of serological test, in 151 subjects of whom 127 had been vaccinated, usually many years before. (From Downie et al., 1969a.)

the titres were lower in early haemorrhagic-type smallpox than in other cases (Sarkar et al., 1967, 1969), but Downie et al. (1969b) found haemagglutinin-inhibiting antibodies in most cases of haemorrhagic-type smallpox, although both neutralizing and complement-fixing antibodies were at much lower levels or absent in such cases.

As might be expected, antibodies usually appeared earlier and reached higher levels in vaccinated than in unvaccinated patients (Downie & McCarthy, 1958).

### Haematological Observations

The blood picture in smallpox varied according to the nature of the case and the stage of the disease. In most cases there was little change in the red blood cell count, but during the eruptive stage the numbers of granular leukocytes usually fell and a relative and absolute increase in the numbers of lymphocytes occurred. The granulocytopenia was often reversed during the late pustular stage, perhaps because of secondary infection of the skin lesions in some cases.

In early haemorrhagic-type smallpox there was often a striking change in the blood picture, which Ikeda (1925) considered to be of diagnostic value. Pathological forms of normoblasts with basophil stippling or polychromatophilia were common; the total

leukocyte count was increased by 30–40%, with a marked augmentation in the numbers of lymphocytes and monocytes; and the presence of myelocytes and myeloblasts suggested an intense stimulation of the bone marrow. In contrast to the rise in the number of platelets found after the vesicular stage in many other cases of smallpox, Ikeda discovered that there was a marked and progressive thrombocytopenia in haemorrhagic-type smallpox, the number of circulating platelets often falling to a very low level.

Sarkar et al. (1968) compared the concentrations of various serum proteins in 28 sera from cases of smallpox of different clinical severity with those of an equal number of normal subjects. The total proteins were unchanged, but albumin was diminished and globulin increased, the increase being associated with fractions  $\alpha_2$  and  $\gamma$ . There was no correlation between the concentrations of any of these proteins and the level of haemagglutinin-inhibiting antibodies.

More detailed studies of the pathophysiology of bleeding were carried out on patients in Madras and reported by McKenzie et al. (1965) and Roberts et al. (1965). Their findings in relation to vascular integrity, platelet function and blood coagulation are summarized in Table 1.8, which illustrates the generality of impaired functions in haemorrhagic smallpox, especially evident in the early type. In contrast to Ikeda (1925), these

Table 1.8. Results of tests for platelet function, vascular integrity and blood coagulation in smallpox<sup>a</sup>

Test	Ordinary-type smallpox (8 patients)	Haemorrhagic-type smallpox (35 patients)	
		Early	Late

<sup>a</sup> Based on McKenzie et al. (1965).

investigators found that many patients with smallpox but with no clinical evidence of haemorrhage had moderate to severe thrombocytopenia but usually no other coagulation defect. Patients with late haemorrhagic-type smallpox had severe thrombocytopenia and some had a mild to moderate decrease in prothrombin and a moderate decrease in accelerator globulin. As expected, the cases of early haemorrhagic-type smallpox were characterized by multiple defects, with significant and specific coagulation defects in addition to severe thrombocytopenia. All had an elevated thrombin time and a total absence of accelerator globulin, which the authors ascribed to disseminated intravascular coagulation. At autopsy such cases showed disseminated intravascular thrombosis involving small vessels in many organs.

## COMPLICATIONS

Complications of two kinds occurred in smallpox. One group was due either directly or indirectly to viral activity in an unusual site, the other to secondary bacterial infection.

### The Skin

As noted earlier, pustulation was part of the natural sequence of development of the skin lesions in smallpox. However, in most countries in the days before antibiotics were available and, even recently, in those in which hygiene was poor and such treatment not obtainable, secondary bacterial infection of the skin lesions often occurred, sometimes to an extent that Ricketts (1908) described as "thousands of boils". In pre-antibiotic days septic complications also occurred in variola minor; Marsden (1936) recorded the presence of boils in 3.65% and of septic dermatitis in 2.3% of his series of cases. Even higher percentages of these complications were seen in the Ogaden desert during the late stages of the eradication programme in Somalia (Ježek et al., 1981).

### Ocular System

Mild conjunctivitis, occurring early in the course of the disease, or at the time of the eruption if there were lesions on the eyelids, was essentially part of the acute disease and not a complication. Sometimes it was the only

symptom (Dekking et al., 1967). Pocks often occurred on the margins of the eyelids but not on the avascular cornea. Often there was much swelling of the eyelids (see Plate 1.13), which made it difficult to open the eyes. Dixon (1962) suggests that it was this swelling, rather than keratitis or corneal ulceration, that accounted for the frequent references in the old non-technical literature that a person was "blind with smallpox". Corneal ulceration and sometimes keratitis did occur in smallpox. These complications were common in haemorrhagic-type smallpox, but were of relatively minor importance because such patients soon died. In ordinary-type smallpox corneal ulceration occurred at about the end of the 2nd week of illness, beginning at the corneal margin. Sometimes the ulcers healed rapidly and there was only a trivial opacity; on other occasions there was severe corneal scarring. Both Dixon (1962) and Rao (1972) note that keratitis and corneal ulceration were far more common in malnourished children than in the well nourished; for this reason these conditions continued to be more important complications in developing countries than in the more prosperous industrialized countries. Mack et al. (1970) reported that 28 out of 405 patients examined within 6 weeks of onset in a rural setting in Pakistani Punjab had corneal lesions, which occurred mostly in patients with confluent or semiconfluent rashes. Three out of 11 patients seen a year later had permanent ocular lesions, and 4 other instances of permanent lesions were observed in 148 cases in whom lesions had not originally been seen. The overall rate of residual corneal opacity in those surviving smallpox was 4.4%. Corneal ulcers occurred in 1% of cases in Rao's series (excluding haemorrhagic-type smallpox) and keratitis in about 0.25%.

### Joints and Bones

Arthritis, associated with involvement of the bones of the joints, was a relatively common complication of smallpox, occurring in 1.7% of cases in Rao's series, usually in children. Cockshott & MacGregor (1958) and Cockshott (1965) reviewed the condition, which they called "osteomyelitis variolosa", and described a series of cases observed in Nigeria. More recently, Gupta & Srivasta (1973) reviewed the X-ray features of 20 cases observed in India. The elbow was the most commonly affected joint and symmetrical

**Plate 1.26.** Osteomyelitis variolosa in an unvaccinated Nigerian child. Joint symptoms appeared 1 week after the onset of rash and affected both elbows. **A:** External appearance, showing hypopigmented spots of healed exanthem and swollen elbows. **B:** X-ray appearances (From Cockshott & MacGregor, 1958.)

bilateral joint involvement was frequent (Plate 1.26). Although secondary bacterial infection sometimes occurred, the disease was primarily due to viral infection of the metaphyses of growing bones. The primary bone lesion was probably a proliferating arteritis, which led to fibrosis, necrosis and bone resorption (Eeckels et al, 1964).

This complication usually occurred late in the course of the disease, after the 15th day, and was accompanied by a brief recurrence of

fever during the scabbing stage. Because of the severity of smallpox itself, and the insidious nature of the bone and joint involvement, cases were often missed during the attack, and only recognized as probably having been due to smallpox years afterwards because of a variety of bone defects for which there were no other explanations (Gupta & Srivasta, 1973).

### Respiratory System

Rao (1972) regarded respiratory complications as common in severe smallpox, especially in the unvaccinated. However, the symptoms he describes, bronchitis and pneumonitis, are better regarded as part of the normal disease syndrome than as complications. Pulmonary oedema was fairly common in haemorrhagic- and flat-type smallpox. Bronchopneumonia due to secondary bacterial infection sometimes occurred and could be serious in debilitated patients. In his long series of cases of variola minor, Marsden (1936) recorded only 7 cases of bronchopneumonia.

Although sometimes responsible for death, pulmonary complications were usually followed by complete recovery. However, coughing could have serious epidemiological consequences, if it occurred during the 1st week of disease, when the oral secretions were most highly infectious (see Chapter 4). A.R. Rao (personal communication, 1981) regarded cough associated with the sticky mucus of bronchitis as a relatively common symptom, especially in unvaccinated individuals. However, its epidemiological consequences were reduced if, as in the majority of cases, it did not become evident before about the 10th day of disease. Epidemiologists engaged in the global smallpox eradication programme regarded cough as a rare symptom in smallpox.

### Gastrointestinal System

Apart from vomiting and, less commonly, diarrhoea during the pre-eruptive stage, gastrointestinal symptoms were rare. Diarrhoea sometimes occurred in the 2nd week and acute dilatation of the stomach was observed, especially in infants, though only rarely (Rao, 1972). Extensive viral infection of the intestinal mucous membrane occurred in some severe cases, especially in flat-type smallpox.

In such cases, which were usually fatal, portions of the mucous membrane were passed as a tubular cast.

### Genitourinary System

Orchitis was uncommon (0.1% in Rao's series) and usually unilateral. This observation casts doubt on the suggestion of Phadke et al. (1973) that smallpox was the single most important etiological factor in obstructive azoospermia in India.

In haemorrhagic-type smallpox, bleeding into the pelvis of the kidney sometimes produced haematuria (see Table 1.6).

### Central Nervous System

Encephalitis was a relatively common complication of smallpox (about 1 in 500 cases in variola major (Rao, 1972) and 1 in 2000 cases in variola minor (Marsden, 1936)). It usually appeared between the 6th and the 10th day, when the rash was in the papular or vesicular stage. Encephalitis contributed little to the case-fatality rate of variola major but was an important factor in the few deaths which occurred in variola minor. Recovery, although sometimes slow, was usually complete.

According to a detailed review by Marsden & Hurst (1932), the symptomatology and the pathological findings in fatal cases of encephalitis associated with variola minor were indistinguishable from those of the encephalomyelitis which occasionally occurs after vaccination or in the late stages of measles. Clinical details are described in Chapter 7, for although it was a much rarer complication (in Madras, for example, 1 in 500 cases of smallpox and 1 in 100 000 cases of primary vaccination (Rao, 1972)), postinfection encephalitis was a much more significant feature of vaccination than of smallpox, since it was then the result of medical intervention in an otherwise healthy subject rather than a rare complication of a severe disease.

### SEQUELAE

In order of their frequency the sequelae seen in persons who recovered from smallpox were facial pockmarks, blindness, and limb deformities.

### Pockmarks

During the first few months after recovery from smallpox the sites of the scabs were abnormally pigmented, hypopigmented in dark-skinned persons and red or hyperpigmented in fair-skinned subjects (Plate 1.27A and B). As the skin regained its normal pigmentation, most cases of variola major, but few of variola minor, were seen to have pitted scars, called pockmarks, in the sites of some of the pustular skin lesions. These were depressed scars 2 mm or more in diameter, usually circular and varying in number from one (which would be difficult to ascribe to smallpox) to several hundreds (Plate 1.27C and D). They resulted from fibrosis in the dermis, and were much more common on the face because of the greater frequency of large sebaceous glands in the skin of the face (Bras, 1952b). Although the rash occurred on the scalp as well, relatively few pockmarks were seen there. In ordinary-type variola major the rash affected the sebaceous glands severely (Bras, 1952b) and permanent facial pockmarks occurred in 65–80% of survivors (Mack et al., 1970; Ježek et al., 1978d). The sebaceous glands were not affected in flat-type smallpox and the few patients who survived this type of infection were rarely severely pockmarked.

When secondary bacterial infection of the pustules occurred the resulting scarring was often more severe and the scars more irregular in shape than after an uncomplicated rash.

In variola minor the rash, though sometimes profuse, comprised shallow lesions that were usually restricted to the epidermis and only rarely involved the sebaceous glands—hence pockmarks were much less common in such cases. For example, Marsden (1936) recorded depressed scars in only 0.7% of his series of cases, although hyperpigmentation was present in about 11% of these fair-skinned subjects at the time of their discharge from hospital. Among persons with more deeply pigmented skins, hypopigmented spots sometimes occurred on the face or elsewhere for several months after recovery (Ježek & Hardjotanojo, 1980) but eventually disappeared.

The observation of facial pockmarks was an important epidemiological tool in smallpox eradication programmes in countries in which the disease was due to variola major, but in those in which variola minor prevailed pockmarking was too infrequent for such

surveys to be of epidemiological value (see Chapters 4 and 24).

### Blindness

Corneal scarring with consequent blindness sometimes followed the keratitis or corneal ulceration which was a rare complication of smallpox (though less uncommon in malnourished individuals). As Dixon (1962) commented, "Every writer on smallpox over the last 150 years has pointed out that in his experience the amount of blindness due to smallpox was much less than that quoted by previous authors". The explanation is probably that the authors quoted were almost always writing of conditions in Europe. During the last 150 years the level of nourishment and hygiene rose steadily among those who formed the subject of these publications, and, as remarked earlier, keratitis, corneal ulceration and corneal scarring rarely occurred in well-nourished patients. Blindness following smallpox remained a serious although uncommon complication in poorer countries (Plate 1.27C and D). Rao (1972) noted 60 patients with keratitis and/or corneal ulcer, of whom 24 had loss of vision in one eye and 1 in both eyes—an incidence of blindness of 0.45% among 5459 survivors. In Bangladesh, Hughes (WHO/SE/78.101) found blindness in 0.9% and corneal opacities in an additional 2.1% of patients examined 1–2 years after recovery from smallpox. All 4 cases of blindness and 7 of the 9 cases of corneal scarring occurred in unvaccinated subjects.

### Limb Deformities

As has been described earlier, osteomyelitis and arthritis were not uncommon complications of smallpox. Many cases resolved without permanent deformity. Because of the severity of the disease itself and the mild symptoms of joint involvement, skeletal manifestations were often missed during the acute infection and recognized years later in the form of bone shortening, flail joints, subluxations and gross bone deformities (Gupta & Srivasta, 1973).

## PROGNOSIS OF VARIOLA MAJOR

The prognosis of a case of smallpox had to be evaluated in terms of the likelihood of death and the possibilities of serious sequelae. In both respects, the prognosis of variola minor was almost invariably good; the vast majority of patients recovered and even facial pockmarks were an uncommon sequel. It is therefore necessary to consider the prognosis only in terms of variola major. As will be further elaborated in Chapter 2, there were geographical variations in the virulence of variola major virus, in terms of the usual case-fatality rates in different parts of the world, which during the period of the Intensified Smallpox Eradication Programme (see Chapter 10) seemed to be uniformly high in the Indian subcontinent and adjacent parts of western Asia and rather lower in Indonesia and western, central and eastern Africa.

### Calculation of Case-Fatality Rates

#### *How representative were hospital-based data?*

The calculation of the case-fatality rate in smallpox was not a straightforward matter. Most data (e.g., Rao, 1972; Guha Mazumder et al., 1975) were based on series of cases treated in hospitals; the question arises of how representative of the total spectrum of cases were those admitted to hospital. Rao's (1972) series was probably representative of cases in Madras; in a personal communication (1981) this author states that between 1961 and 1969, 80–90% of all cases in Madras were admitted to the city's Infectious Diseases Hospital, the proportion between 1965 and 1969 being almost 100%.

This was not true of other areas, especially where rural populations were involved. Koplan et al. (1978) investigated this problem in Bangladesh, from which smallpox had been eliminated in 1970 only to be reintroduced by refugees returning from India in 1972. Table 1.9 compares the age- and sex-specific case-fatality rates pertaining to 346 cases admitted to the Dhaka Infectious Diseases Hospital during the period March 1972 to April 1973 with those of 502 non-hospitalized cases diagnosed by specially trained surveillance teams in a rural area in the Noakhali District in south central Bangladesh during the period July 1972 to February 1973. The age and sex distributions of the two sets of data are very

similar; when the rates were applied to a standard Bengali population the overall case-fatality rates were only changed from 51% to 52% for the hospitalized patients and from 21% to 23% for the village patients, a highly significant difference between the two sets of data.

The explanation is complex and lies in a number of factors which would probably differ in importance in different places, but which must always be borne in mind when considering case-fatality rates based on hospitalized series of cases in countries in which smallpox was endemic. In Bangladesh, hospi-

tal admission reflected a high proportion of patients who were too ill to travel back to their villages or too sick to hide their illness within the community, whereas the village data essentially referred to every case in the community.

### Effects of Immunity

#### *Immunity after an attack of smallpox*

A person who had recovered from smallpox had a high degree of immunity to reinfection, which usually lasted throughout life, but

Table 1.10. Protection against challenge vaccination with vaccinia virus among persons who had recovered from smallpox<sup>a</sup>

(1978).<sup>e</sup> Data from Ježek et al. (1981).<sup>f</sup> Data from Vichniakov (1968).

second attacks did occasionally occur. Rao (1972) noted about 1 repeat attack per 1000 cases, the average interval between the attacks being 15–20 years. This refers to clinical disease, confirmed by laboratory investigation, in pockmarked persons. Serological examination of exposed contacts would probably have revealed that second subclinical infections were much more common; subclinical infection was not uncommon in vaccinated contacts (Heiner et al., 1971a). However, subclinical infections were of little epidemiological importance, except as boosters of immunity, since subjects with such infections did not transmit them.

Another measure of the persistence of resistance following smallpox was provided by determining the response of persons known to have had smallpox to challenge vaccination with vaccinia virus. Interpretation of the results (Table 1.10) is complicated by the fact that many of those who had had variola major had also been vaccinated, a procedure which enhanced immunity to challenge vaccination (Zikmund et al., 1978). A substantial proportion of persons exhibited a major response to vaccination as early as 1 year after recovery from variola minor, and even after variola major resistance to challenge vaccination was low in half the subjects tested 6–11 years after recovery from the disease. In variola major immunity to challenge vaccination persisted for much longer in those who had had a severe attack of smallpox than in those who had suffered only a mild attack (Vichniakov, 1968). As far as heterologous immunity is concerned, it appears that vaccination protected against naturally transmitted smallpox (see below and Chapter 7) rather more effectively than smallpox modified the response to vaccination. This may have been mainly due to the dose of virus and the manner of its implantation: a large dose introduced into the skin in vaccination and a small dose implanted on the respiratory mucosa in smallpox.

#### *Immunity after vaccination*

The effects of vaccination on preventing infection will be discussed in Chapters 7 and 11; here we are concerned with the effects of vaccination and/or revaccination on the severity of smallpox in vaccinated persons who did contract the disease. There are several difficulties in evaluating these effects. There were some patients who said that they had

been vaccinated (or revaccinated) but had no scar; Rao (1972) classed these as "unsuccessfully vaccinated". However, even in Madras some of these persons may have been successfully vaccinated, with vaccine of low potency applied over a small area of skin, leaving no scar; such misdiagnoses of vaccination status may account for the difference in prognosis between the "unvaccinated" and the "unsuccessfully vaccinated" in Rao's data (case-fatality rates in ordinary-type smallpox of 36.9% and 27.2% respectively). Among those with a vaccination scar there were other problems. First, did the scar really result from the replication of vaccinia virus in the skin? Secondary infection without viral replication could cause scars, especially when the rotary lancet was used with an unsatisfactory liquid vaccine. Secondly, how long ago did the last successful vaccination (or revaccination) occur? These questions could not always be accurately answered, but it is important to bear them in mind when considering the effects of vaccination on the prognosis of smallpox. Finally, the studies of Heiner et al. (1971a) showed that in endemic areas subclinical infection with variola virus occurred rather frequently among vaccinated persons, thus boosting their immunity.

Data published by Hanna (1913) from an outbreak of variola major in Liverpool, England, in 1902–1903, illustrate clearly the ameliorating effect of childhood vaccination on the severity of smallpox (Table 1.11). There was a striking difference between vaccinated and unvaccinated patients in all age groups, both in the spectrum of severity and in case-fatality rates. Protection waned with age—i.e., with increasing intervals since vaccination—but was substantial even in those aged more than 50 years.

Rao's data (see Table 1.2) confirm the extent of the protection against death provided by vaccination; the overall case-fatality rates in vaccinated and unvaccinated (including "unsuccessfully vaccinated") persons in his series were 6.3% and 35.5% respectively.

Hanna's conclusions on the duration of protection against death provided by vaccination, in those who got smallpox, is confirmed by data collected by Mack (1972), who analysed 680 cases of variola major occurring after importations of the disease into Europe and Canada during the period 1950–1971 (Table 1.12). The case-fatality rate was 52% in unvaccinated persons, 1.4% in those vaccinated 0–10 years before exposure, and only

11% in those vaccinated over 20 years before exposure. The contrast is even more striking if only the age group 10-49 years is considered: a case-fatality rate of 49% in the unvaccinated and one of 4.3% in those vaccinated over 20 years earlier.

Before 1967 it was a common practice in India, as it had earlier been in Great Britain and elsewhere, to make several insertions of vaccinia virus at adjacent sites. Early in the Intensified Smallpox Eradication Programme it was decided that vaccination should routinely be carried out on one site only (see Chapter 11), but some older data suggested that there was a correlation between protection and scar area (allowing for changes in the area with growth) and/or the number of insertions. For example, Hanna (1913) report-

ed that the mildest attacks of smallpox occurred in those with the largest scar areas, while at all ages the average scar areas of vaccinated contacts who did not get smallpox was substantially larger than in those who did. Likewise, Rao (1972) reported a case-fatality rate of 16.4% among 79 cases of ordinary-type smallpox in persons aged 0-9 years with only 1 scar, compared with no deaths among 70 cases in comparable individuals with 2, 3 or 4 scars.

#### Passive immunity

Apart from reports of the deliberate use of anti-orthopoxvirus serum for serotherapy, some information has been gathered on the effects of passive immunity resulting from the

vaccination of pregnant women during the incubation period of smallpox on the resistance of the fetus and the newborn child. Pregnant women were particularly susceptible to the effects of smallpox (see below), and abortion often occurred. Nevertheless, it was found that some women who had been vaccinated during the incubation period of their attack went to term and bore live babies who were usually resistant to smallpox, presumably because of passive immunization.

### Effects of Age

Smallpox affected persons of all ages; the age incidence of the disease in endemic countries reflected the particular epidemiological characteristics of the population at the time (see Chapter 4). Some relevant data on the relation of age to prognosis in cases of variola major occurring in unvaccinated subjects are provided in Tables 1.9 and 1.11; additional statistics from India are shown in Table 1.13 and data for Pakistan are given by Mack et al. (1970). All these figures accord with the general impressions of most epidemiologists with extensive experience of smallpox and are consistent with the usual pattern of age-related susceptibility to death from acute infectious diseases (Burnet, 1952). Mortality was very high (usually over 40%) in infants, fell to its lowest level in children, and then rose with increasing age. The low case-fatality rate in unvaccinated children is significant in that the famous variolators in Great Britain during the 18th century, such as

the Suttons, selected healthy children for this procedure (Razzell, 1977b), which may partly account for the low mortality it caused.

Such deaths as did occur in variola minor were predominantly in very young children. Suzart de Carvalho Filho et al. (1970) recorded an overall case-fatality rate of 0.8% in Brazil in 1968-1969, but the rate was 16.7% among patients aged less than 3 months and 2% in the age group 3-12 months (see Chapter 12, Table 12.16).

### Effects of Pregnancy

It is universally agreed that smallpox was more severe in pregnant women than in non-pregnant women or in men, irrespective of vaccination status. Table 1.14 sets forth the distribution of clinical types of smallpox in Rao's series, in pregnant and non-pregnant women and in men in the age group 15-44 years, according to vaccination status. Although pregnant women constituted only 11.6% of the series, 50% of the cases of haemorrhagic-type smallpox occurred among them, mostly in women who had been vaccinated in infancy; indeed, almost one-quarter of all cases of smallpox in pregnant women were of the haemorrhagic type. Flat-type smallpox was over twice as common among pregnant women (3.4% compared with 1.5%) whereas modified-type smallpox was less than half as frequent (9.4% compared with 21.2%).

The effects of smallpox on the fetus or the newborn infant were also severe (Table 1.15) but congenital smallpox was not often diag-

nosed among those born alive. Ten cases were recognized among the live births in Rao's series, but because their mothers had died many infants also died within a few days of birth and it was not determined whether they had smallpox or not. Smallpox caused premature termination of the pregnancy in 75% of women who got the disease during the early weeks of pregnancy and in 60% of those who contracted it after the fetus had become viable but before it had reached full term.

to some extent on the physiological factors just discussed, but clinical type provided much the best basis for the prognosis of individual cases. Haemorrhagic- and flat-type smallpox were almost always fatal and among cases of ordinary-type smallpox the extent of the rash (confluent, semiconfluent or discrete) was of prognostic value. Modified-type smallpox was very rarely fatal.

## DIFFERENTIAL DIAGNOSIS

### Clinical Type of Disease

Whether flat- or haemorrhagic-type smallpox developed in particular persons depended

The problems involved in the diagnosis of smallpox during an epidemic or in a situation in which the disease was endemic were of a

different nature from those in suspected importations into non-endemic countries or regions. There were three elements in the diagnosis: clinical, epidemiological, and laboratory. No one diagnostic approach was always sufficient in itself. The clinical diagnosis of ordinary-type smallpox after the rash had developed was not difficult, and most cases were of this kind. But there were often patients in whom an accurate diagnosis could not be made on clinical grounds alone, at any rate at the first examination, early in the course of the disease. In such cases the epidemiological circumstances of the suspected case often provided a valuable lead. Nor was it wise to trust implicitly a positive report from the laboratory, if it ran counter to clinical and epidemiological evidence. Like everyone else, laboratory workers sometimes made mistakes, and clerical errors were always a possibility.

The clinical diagnosis of the great majority of cases of smallpox rested on the characteristic features of the pre-eruptive fever, the order of appearance of the rash (first on the face, then on the forearms, trunk and lower limbs), the evolution of the individual lesions, from macule to vesicle and pustule, and the appearance and feel of the vesicle and pustule. Furthermore, the lesions on any particular part of the body were all at more or less the same stage of development. The distribution of the skin lesions was also of great diagnostic value, with relatively few lesions on the trunk but many on the face and arms (more on the extensor than the flexor surfaces) and on the lower limbs, and on the palms of the hands and the soles of the feet. The major difficulties in differential diagnosis of ordinary-type smallpox arose in cases modified by vaccination, in which the lesions were often sparse and abnormal in appearance and underwent an accelerated course of evolution.

The diagnosis of flat-type smallpox was also relatively straightforward, but haemorrhagic-type smallpox, especially the early subtype and both forms in the early stages, was usually impossible to diagnose without laboratory assistance, and the diagnosis was often missed in non-endemic situations in which smallpox was not thought of by the attendant physician.

Diagnosis of smallpox in the pre-eruptive stage was impossible on clinical grounds alone, although it would have been suspected if epidemiological considerations (exposure to a known case, lack of vaccination) had been suggestive. The differential diagnosis of

smallpox at this stage of the disease will therefore not be discussed here.

### Ordinary- and Flat-Type Smallpox

The diseases involved in the differential diagnosis of ordinary- and flat-type smallpox were essentially those causing fever with rash.

#### *Human monkeypox*

Although a rare disease, human monkeypox ranks first among the diseases that might be confused with smallpox, because differential diagnosis was impossible on clinical grounds alone, although gross lymphadenopathy was found in most cases of monkeypox and not in smallpox (see Chapter 29). In the field, diagnosis depended on the occurrence of a disease indistinguishable from ordinary-type smallpox in the appropriate epidemiological situation: a particular geographical area (western and central Africa), no endemic smallpox, and the appropriate environmental surroundings (a small village in a tropical rain forest). Laboratory confirmation was essential, either by recovery of the virus from lesion material or retrospectively by appropriate serological tests.

#### *Chickenpox*

This disease of world-wide occurrence was the single most important infection to be considered in the differential diagnosis and was particularly important in three circumstances: in countries in which variola minor was endemic, in vaccinated individuals, and in situations in which chickenpox occurred rather frequently in adults, often as a severe disease, as in several parts of India. For example, in post-eradication searches in India in 1976, 63% of the "suspected smallpox" cases were in fact cases of chickenpox (Ježek et al., 1978e).

In the usual case of chickenpox the nature, distribution and evolution of the rash are quite distinctive (Plate 1.28). The skin lesions in chickenpox are much more superficial than they were in smallpox. They appear in "crops" so that at any time lesions of various ages may be found on the same part of the body and their distribution is "centripetal" (denser on the trunk than the face and extremities) rather than "centrifugal", as in smallpox.

**Plate I.27.** Sequelae of smallpox. Shortly after recovery the sites of pustules are usually depigmented in dark-skinned subjects (A) or red in fair-skinned subjects (B). Most cases of variola major leave facial pock marks, which may be deeply pigmented (C); blindness is a rare complication (C and D). (B from Herrlich et al., 1967.)

**Plate 1.28.** Chickenpox. On the 3rd day of rash (**A**, **B** and **C**) pocks are at different stages of development: papules, vesicles, pustules and scabs. On the 7th day of rash (**D**) all pocks are scabbed. There are many lesions on the trunk (**B**) and few on the limbs.

**Plate 1.29. A:** Measles. There is a blotchy generalized rash, as well as a runny nose and sore eyes. **B:** Secondary syphilis. The rash had a different distribution from that of smallpox, did not feel "shotty" and did not progress to pustules and scabs as in smallpox. (From Lambert & Farrar, 1982). **C:** Erythema multiforme.

**Plate I.30.** A and B: Drug eruptions, which sometimes occurred in patients with smallpox. C and D: Meningococcal septicaemia, which could be difficult to differentiate from early haemorrhagic-type smallpox. (B, C, D from Lambert & Farrar, 1982.)

Difficulties arose with severe chickenpox in adults (White, 1978), a disease found especially in some parts of India (Kerala, Tamil Nadu (formerly Madras State), and West Bengal). Indeed, some severe cases of chickenpox in adults were associated with such an extensive rash, including lesions on the palms and soles, that it was impossible to be certain at any stage of the disease as to whether it was chickenpox or smallpox. During the eradication programme, all such cases were regarded as smallpox and appropriate control measures were undertaken. Sometimes the lesions in this type of chickenpox were haemorrhagic, and it was in these cases that the rate of development of the rash and its distribution were important diagnostic features.

Such severe cases of chickenpox have always been rare. Diagnostic problems occurred more frequently between attacks of chickenpox of ordinary severity and mild, particularly vaccine-modified, attacks of smallpox. In vaccine-modified smallpox the lesions were often superficial, not "shotty"; they dried up quickly with a small scab and left scars very little different from those of chickenpox. Differential diagnosis was often impossible on clinical grounds alone; laboratory confirmation was essential.

Since they had the same seasonal incidence, smallpox and chickenpox might sometimes have been expected to occur concurrently in the same patient. Sarkar et al. (1976) report 3 such cases from a refugee camp near Calcutta in 1972, in males aged 15, 30 and 60 years respectively, all with vaccination scars. All the patients survived, the clinical course of each disease being unaffected by the other. The diagnosis of smallpox was confirmed in every case by the examination of material from variola-like lesions, and varicella virus was detected by electron microscopy in vesicle fluid from a chickenpox-like lesion in the one case that was examined by this technique.

### *Tanapox*

This poxvirus disease occurs as a zoonosis in parts of Kenya and Zaire, and probably elsewhere in Africa (see Chapter 29). The lesions are usually single, and few in number if they are multiple. They are nodular rather than pustular and evolve much more slowly than the lesions of smallpox. However, when first seen, such lesions could be confused with those of mild smallpox in a vaccinated subject.

The slow course and absence of pustulation would subsequently clarify the diagnosis. Electron microscopic examination of lesion material reveals virions similar to those of variola virus. However, tanapox cannot be cultivated on the chorioallantoic membrane.

### *Measles*

In the first 2 days of the rash, before vesicles developed, the most likely cause of confusion was measles (Plate 1.29A), and this difficulty could persist for several more days in flat-type smallpox, although the severity of this disease was much greater than that of measles. The presence of Koplik's spots was, of course, diagnostic of measles, and in any case the difficulty disappeared as the rash evolved. Historically, measles did not present a problem in countries with endemic smallpox, but in non-endemic countries an early case of smallpox was sometimes diagnosed as measles, with possibly serious consequences in terms of secondary cases. On the other hand, in countries in which smallpox was endemic, physicians were often prone to diagnose all outbreaks of rash associated with deaths as smallpox and to report them as such to the health authorities. Some of these outbreaks later proved to be due to measles.

### *Syphilis*

Earlier writers, e.g., Councilman (1907) and Ricketts (1908), paid considerable attention to syphilitic rashes as presenting a problem in differential diagnosis. With the advent of penicillin and the consequent reduction in the incidence of syphilis—especially of secondary syphilis—in the developed countries, the disease has ceased even to be mentioned by writers, such as Christie (1980), dealing with the general domain of infectious diseases. However, in African countries and India secondary syphilis remained a disease to be considered in the differential diagnosis of smallpox, up to the time of eradication. The roseolar and papular syphilitic rashes (Plate 1.29B) varied in size and distribution and felt different from those of smallpox. The individual lesions were sometimes hard, but they could not be rolled between the thumb and forefinger, to give the "shotty" feel characteristic of the smallpox vesicle. Neither could they be "split" by passing a needle horizontally through the lesion, as could the vesicles of smallpox. The

distribution was also different; if there were a profuse rash on the face, there would also be an equally dense rash on the chest and abdomen and the toxæmia would have been too slight for a case of smallpox with such a rash. Finally, the diagnosis would be clinched by the fact that the papules of syphilis did not evolve further, to vesicles and pustules, like those of smallpox.

### *Erythema multiforme*

This disease (Plate 1.29C) could cause difficulties at any stage of the rash; the distribution of lesions is sometimes very like that of smallpox. In both diseases the patient could be quite ill and have a profuse vesicular eruption particularly affecting the extremities. However, the history is completely unlike that of smallpox: the onset of symptoms and rash tend to coincide and the rash evolves very rapidly to the vesicular stage. Further, erythema multiforme is almost always accompanied by stomatitis, and often by conjunctivitis and urethritis.

In severe cases there could be confusion with flat-type smallpox, since the vesicles were occasionally soft, superficial and flat, individually resembling those of flat-type smallpox. They sometimes coalesced and produced large bullae, also seen in some cases of severe smallpox. The degree of malaise was usually not like that seen in flat-type smallpox, where the patient at this stage had only about 48 hours to live, but the most important difference was in the speed of evolution of the rash in the two diseases. In smallpox with this skin picture the patient would have been ill and getting progressively worse for at least 10 days and the vesicular eruption would have only just fully emerged; in erythema multiforme the rash develops with the onset of constitutional symptoms and evolves rapidly to the vesicular stage.

### *Lesions due to vaccination*

Generalized vaccinia, described in Chapter 7 (see Plate 7.7), rarely caused confusion; the history of vaccination and the nature and distribution of the rash differed substantially from what was found in smallpox. However, problems of precise diagnosis sometimes arose in smallpox contacts who had been vaccinated during what turned out to be the incubation period of smallpox. They usually showed a positive take at the vaccination site and often

a modified rash, which could have been caused by variola or vaccinia virus. Operationally, all such cases were regarded as smallpox from the point of view of management. Precise diagnosis could be made by the culture of virus from several of the vesicles or pustules.

### *Drug eruptions*

Although less important in countries in which smallpox was still endemic, drug eruptions (Plate 1.30A and B) were an important diagnostic problem in countries in which smallpox had been eradicated years before and doctors rarely considered the possibility of the disease. Many instances exist in which the rash of an imported case of smallpox, and sometimes the rashes of second generation cases deriving from it, were diagnosed as drug rashes, since the sick patients had customarily been treated with some kind of drug for the pre-eruptive fever. The diagnosis usually became quite clear with the passage of time and the evolution of the rash, but vaccine-modified smallpox could continue to mislead the physician if he had never considered smallpox as a possible diagnosis.

In endemic countries in recent years, since a wide variety of drugs have become available, cases of smallpox and drug eruption sometimes occurred coincidentally. Rao (1972) described a case in which the drug rash completely obscured that due to smallpox and the diagnosis was only made when variola virus was recovered from some "seeds" extracted from the palms of the hands.

### *Rashes due to other causes*

There are few diseases characterized by a rash that did not at some time suggest a diagnosis of smallpox, occasionally with dramatic effect in non-endemic countries. Acne, scabies and insect bites may be mentioned as examples. Coxsackievirus infections could pose a problem (Mukherjee et al., 1976), and in countries in which both diseases were endemic, dengue haemorrhagic fever and other arbovirus infections associated with a rash were sometimes initially diagnosed as smallpox.

## **Haemorrhagic-Type Smallpox**

Haemorrhagic-type and flat-type smallpox were sometimes associated with a severe

shock-like condition, loss of muscle tone and a peculiar state of apprehension and mental alertness that were said to be unlike the manifestations of any other infectious disease. The occurrence of a petechial rash, especially in the groin and along the flanks to the axillae, was regarded as diagnostic of smallpox, since other forms of febrile purpura, due to meningococci or other organisms, did not have such a localized and symmetrical distribution; but an accurate diagnosis was impossible without laboratory aid. The literature on outbreaks following the importation of smallpox into non-endemic countries (see Chapter 23) is replete with instances in which the index case or sometimes a first generation case, presenting as an acutely fatal case of haemorrhagic-type smallpox, was almost always misdiagnosed as meningococcal septicaemia (Plate 1.30C and D) or acute leukaemia. However, meningococcal bacteraemia is usually more rapidly lethal than was haemorrhagic-type smallpox; acute leukaemia is less rapid.

Erythematous rashes on the face and later on the arms and trunk sometimes suggested the diagnosis of toxic scarlet fever, but the early rash in haemorrhagic-type smallpox was a diffuse not a punctate erythema, the temperature was lower than in severe scarlet fever and the tongue and fauces were practically normal.

Even in endemic areas, and at times when variola major was a common disease, it was very difficult to diagnose very severe smallpox, whether of the haemorrhagic or of the flat type, in its early stages. It can be readily understood why the diagnosis was so often missed in non-endemic countries.

### Effects of Prior Vaccination on Symptomatology

From the diagnostic point of view it was important for physicians to appreciate that there was great individual variation in the extent to which vaccinia immunity persisted. The person presenting with symptoms suggestive of flat-type smallpox, who had had a successful primary vaccination within 5 years, was unlikely to be suffering from this disease; the probability of another diagnosis should therefore have been seriously considered. On the other hand, the presence of signs or symptoms suggestive of a very mild attack of smallpox should not have led the doctor to discount the diagnosis even in the face of an apparently successful vaccination within a year. It was also important to remember that exceedingly mild smallpox, even variola sine eruptione, could occur in persons who had no evidence of ever having been successfully vaccinated.

### Alternative Diagnoses

Several authors have summarized alternative diagnoses that have been made in suspected but unconfirmed cases of smallpox. Table 1.16 lists final diagnoses made in cases of suspected smallpox in situations in which variola major was the expected form of the disease (England and Wales, 1946-1948; India, 1976) and in those in which the endemic disease was variola minor (Somalia, 1977-1979). The overriding importance of chickenpox is apparent in all series. Marsden (1936) also reported that chickenpox was by far the commonest disease to be initially mistaken for variola minor in England (31% of 994 cases of suspected but unconfirmed smallpox). Other conditions suspected to be smallpox included almost all diseases that produced a rash.

### LABORATORY CONFIRMATION OF SMALLPOX DIAGNOSIS

Laboratory methods played a crucial role in the global smallpox eradication programme; indeed, eradication could not have been confidently certified to have been achieved without their use. A detailed historical description of the laboratory methods used for the diagnosis of smallpox is presented in Chapter 2 and an account of the development of laboratory support for the Intensified Smallpox Eradication Programme is given in Chapter 10.

As well as being of critical importance in the global smallpox eradication programme, laboratory methods were also useful for the confirmation of clinical diagnoses. Indeed, although laboratory workers could make mistakes, the recovery of variola virus from a skin lesion was usually regarded as conclusive evidence that a particular patient was or had been suffering from smallpox. Such confirmation was rarely sought in endemic countries when smallpox was a common disease. Any doubtful case was always regarded as smallpox; containment and vaccination procedures operated independently of and were initiated before laboratory confirmation. However, laboratory confirmation or refutation of suspected smallpox was a valuable procedure in non-endemic countries and in smallpox-free regions of the endemic countries as eradication approached.

If an electron microscope was available, the examination of material from vesicles, pus-

tules or scabs, examined by the negative staining technique, could give a rapid presumptive diagnosis of poxvirus, or sometimes herpesvirus, infection. Definitive diagnosis depended on the isolation of the causative virus on the chorioallantoic membrane of the developing chick embryo and its further characterization, if necessary, by biological tests. Usually the character of the pocks produced on the chorioallantoic membrane was distinctive enough for the diagnosis of variola, vaccinia, monkeypox or herpesvirus infection to be made (see Chapter 2).

In the period before the Intensified Smallpox Eradication Programme was launched, gel-precipitation tests were employed extensively in some national programmes (e.g., in India; Basu et al., 1979), and by laboratories that did not have an electron microscope. With adequate amounts of recently collected vesicle fluid it was an accurate and rapid test (World Health Organization, 1969a; A.W. Downie, personal communication, 1981), and when antivariella serum was employed in parallel tests it could be used to differentiate smallpox from chickenpox (Brunell et al., 1971; A.R. Rao, personal communication, 1981).

### TREATMENT: PROPHYLACTIC AND CURATIVE

No disease better illustrated the adage "Prevention is better than cure" than smallpox. Nevertheless, until 1975 millions of persons were infected with variola major virus and, as the foregoing description of its clinical features bears witness, it was a horrible disease with a high case-fatality rate. Any treatment that would ameliorate the severity of the disease in those who were infected would have been welcomed.

In this section, treatment administered after exposure and thus during the incubation period is called "prophylactic" and treatment given after the development of symptoms "curative". Three procedures were used or investigated: vaccination after exposure, immunoprophylaxis and immunotherapy, and chemoprophylaxis and chemotherapy.

#### Vaccination during the Incubation Period

The sheet anchor of smallpox control during the Intensified Smallpox Eradication

Programme was surveillance and containment (see Chapter 10). Containment was possible because vaccination provided protection against infection for those who had not already been infected with variola virus. However, vaccination must also be discussed as a form of prophylactic treatment, for it also modified the progress of the disease in persons vaccinated during the first few days of the incubation period. The precedent for this concept was Pasteur's demonstration of protection against rabies by vaccination during the incubation period. The different time-scales of the pathogenesis of vaccinia and variola (see Fig. 1.3 and Fig. 3.1 of Chapter 3) provided hope that such prophylactic treatment, if carried out during the first week of the incubation period of smallpox, might ameliorate or sometimes abort the disease. Precise data were difficult to obtain, because it was rarely known whether or when a contact had actually been infected with variola virus. Unless sophisticated serological tests had been carried out (and this was never done) it would have been impossible to differentiate between a person sustaining only vaccination and one who had also been incubating smallpox but in whom that infection had produced no symptoms. However, all observers agree that persons in whom smallpox developed a week or more after primary vaccination often had a modified attack. Dixon (1962) summarized his review of the older literature by saying that "at least 50% of cases where successful primary vaccination had occurred during the first week [of the incubation period] will get some vaccine-modification and reduction of severity, whereas when done at a later period the number showing such modification is not likely to be over 20%". In fact, on theoretical grounds the degree of modification might be expected to be highly dependent on the exact timing of infection with variola virus and vaccination; the more nearly these corresponded, the greater was the degree of protection. Without distinguishing the timing of primary vaccina-

tion, Rao (1972) observed a frequency of modified-type smallpox of 8.8% among those given primary vaccination after exposure, compared with 1.0% among unvaccinated patients.

Successful revaccination would have been expected to be even more effective, because of the accelerated immune response.

### Immunoprophylaxis and Immunotherapy

Although the procedure was rendered superfluous by the development of effective measles vaccines, measles could be aborted or ameliorated by the administration of immune gamma-globulin during the first 7 days of the incubation period (Janeway, 1944). During the 1960s some experimental work was carried out in animals (see Chapter 3), and a few trials were made in human beings, to determine whether immunoprophylaxis or immunotherapy might be useful in smallpox.

The most comprehensive trials were carried out in Madras (Kempe et al., 1956, 1961). Immune gamma-globulin, prepared from the serum of recently vaccinated adults (not smallpox convalescents) was administered to close contacts of smallpox cases, most of whom were also vaccinated or revaccinated at the same time. The results of these and other trials (Marennikova, 1962), summarized in Table 1.17, indicate that if given during the incubation period vaccinia-immune gamma-globulin provided protection additional to that expected from vaccination at that time. The greater potency against variola virus of homologous antiserum from smallpox convalescents (Downie & McCarthy, 1958; Downie et al., 1961b) might have been expected to give even better results, but no trials were ever made with such sera. In any case vaccinia-immune or variola-immune gamma-globulin were available in such small quantities that they could only have been used in unusual situations. However, vaccinia-immune gamma-globulin did appear to have a place in the prevention and treatment of vaccination

Table 1.17. Seroprophylaxis of smallpox: effects of vaccinia-immune gamma-globulin on the occurrence and severity of smallpox in vaccinated case contacts

complications in some especially susceptible individuals (see Chapters 7 and 11).

### Chemoprophylaxis and Chemotherapy

It is not surprising that orthopoxviruses, being the largest and most complex viruses, were among the first for which antiviral agents were developed that were effective in inhibiting viral replication in cells (see Chapter 2). Some of these drugs also had activity against orthopoxvirus infections in mice and they were subsequently tested for the treatment and chemoprophylaxis of smallpox. The results were disappointing, in that none was effective in treatment, and chemoprophylaxis was of marginal value only and did not compare in effectiveness with the vaccination of contacts.

#### *Thiosemicarbazones for chemotherapy*

The effectiveness of certain thiosemicarbazones in the treatment of tuberculosis led to the demonstration by Hamre et al. (1950) that some thiosemicarbazones reduced the mortality of mice inoculated with vaccinia virus. This led to the testing by pharmaceutical companies of many different thiosemicarbazones, two of which (*N*-methylisatin  $\beta$ -thiosemicarbazone (metisazone (methisazone)) and 4-bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone (M & B 7714)) appeared to be particularly effective against variola in mice (Bauer & Sadler, 1960; Rao et al., 1965). Clinical trials for the treatment and prophylaxis of smallpox were car-

ried out in Madras (see reviews by Bauer (1972) and Rao (1972)).

Both drugs were only slightly soluble and were given as tablets or as a micronized preparation in syrup. The main side-effects were nausea and vomiting, which were sometimes severe. Rao et al. (1966a, 1969b) carried out double-blind trials of both thiosemicarbazones (Table 1.18). The only apparent differences between the treated and control groups were small reductions in the already low case-fatality rates in vaccinated subjects. However analysed, there were no significant differences in case-fatality rates between the unvaccinated treated subjects and the controls; nor were there any significant differences in symptomatology among the small number of cases of ordinary-type smallpox whom it was possible to treat as early as the 5th day of disease (2nd day of rash).

#### *Thiosemicarbazones for chemoprophylaxis*

Clearly, these thiosemicarbazones were useless for the treatment of smallpox. However, Bauer et al. (1963) had claimed impressive results in chemoprophylaxis with metisazone in a trial in Madras. Most of the case contacts had been vaccinated during infancy and again shortly after detection of the index cases. Among 1100 subjects treated with metisazone there were 3 cases of smallpox and no deaths. Of 1126 controls not given the drug, 78 developed smallpox and 12 died. The result was hailed enthusiastically: "...if further experience of this substance leads to equally favourable conclusions, the work...will perhaps rank as the most significant advance

### A Comment on Chemoprophylaxis in Smallpox

"The major drawback to routine use of the drug [metisazone] is the frequency of often severe nausea and vomiting which occurs in not less than 25% and more often in two-thirds or more. In presently endemic countries, use of the drug is wholly impractical, not only in terms of acceptance on the part of the population, but because of the logistics involved in giving it. It has been difficult enough to persuade health administrators of the need for immediate investigation and control of all outbreaks and even more difficult to establish the mechanics for doing this properly. Use of methisazone would require not only administration of the drug but repeat visits to determine whether vomiting had occurred and, if necessary, repeat administration of the drug. This cannot be considered.

"In the non-endemic developed countries, one could more easily cope with the logistics of administration. It is noted, however, that vaccinia immune globulin has been shown to have a protective efficacy of the same order of magnitude as methisazone but without the associated toxic side effects." (D.A. Henderson, unpublished report, December 1970.)

in smallpox control since the days of Jenner" (*Lancet*, 1963). Such a comment was perhaps pardonable in Great Britain at a time when there were rather frequent importations of variola major from the Indian subcontinent. Statements in the Indian press, such as "at last a drug has come to replace the much dreaded vaccination" (quoted by Rao, 1972), were more serious in their implications for the control and eradication of smallpox.

There were major defects in the design of this trial: treatment and control groups were not allocated at random, contacts were not visited daily, and assessment of the taking of the drug (which caused nausea and vomiting) was made by questioning at a second visit 2 weeks after supplies of it had been distributed. Further trials with metisazone gave variable but mostly favourable results, which are summarized in Table 1.19. Rao et al. (1966b) reported a less favourable but still significant result with unvaccinated contacts given M & B 7714 as a chemoprophylactic drug.

The overall conclusion is that, given prophylactically, metisazone did exert some protective effect, but its administration was often associated with severe nausea and vomiting. Health administrators considered its use in countries in which smallpox was still endemic in the late 1960s and early 1970s as "wholly impractical" (see box) in terms of acceptability by the populations concerned and the logistics of administering it. In non-endemic countries these difficulties would be less serious but in these situations vaccinia-immune globulin, which had a protective effect of the same magnitude as metisazone, without toxic side-effects, was available. Prompt vaccination or revaccination of contacts remained the sheet anchor of prophylaxis until smallpox was finally eradicated.

#### Cytosine arabinoside

In an uncontrolled trial in Bangladesh, Hossain et al. (1972) reported promising

results with cytosine arabinoside in the treatment of variola major. However, subsequent controlled studies in both variola major (Monsur et al., 1975) and variola minor (Dennis et al., 1974) provided no evidence of any effect on either the mortality (in variola major) or the clinical progression of the disease. Nor was the related drug, adenine arabinoside, of any use (Koplan et al., 1975).

### Symptomatic Treatment

In the absence of any effective therapy for established cases of smallpox, treatment was symptomatic and demanded above all good nursing care, which put great demands on the devotion and skill of the nursing staff. In the crowded smallpox hospitals in endemic countries most nursing care was in fact provided by

members of the patient's family, who often came to stay in the hospital.

In endemic countries, in which hospital facilities were often poor, patients were usually better looked after at home in their village surroundings. Koplan et al. (1978) showed that the case-fatality rate was substantially higher in hospitals than in village surroundings, mainly because only the more severe cases, often in persons without local family support, were admitted to hospital, and devoted family care was better than the nursing provided in grossly overcrowded hospitals. Another reason for encouraging treatment at home during the Intensified Smallpox Eradication Programme was the frequency with which smallpox was transmitted to other patients in hospitals, which often left much to be desired in terms of their overall administration and management of other patients, visitors and staff.

## Day 1

**Plate 1.4.** This and the next 10 colour plates illustrate the evolution and subsequent healing of the skin lesions in a 9-month-old unvaccinated Pakistani child. The rash appeared 1 day after the onset of fever, and the illustrations are categorized in terms of the day of rash. Each plate shows the ventral surface of the full body, the face, and the upper arm. This plate illustrates the first day of the rash. A few small papules are visible on the face and upper arm. An enanthem would usually have been present in the oropharynx at this time, but cannot be seen in this photograph (see Plate 1.3C).

**Day 2**

**Plate 1.5.** Second day of rash. More papules are present, having appeared first on the face and the upper part of the extremities.

**Day 3**

**Plate I.6.** Third day of rash. Additional lesions continue to appear and some of the papules are becoming obviously vesicular.

**Day 4**

**Plate I.7.** Fourth day of rash. All lesions had usually appeared by this time. Those that appeared earliest, on the face and upper extremities, are somewhat more mature than those that appeared later on other parts of the body, but on any specific area of the body all lesions are at approximately the same stage of development. Lesions are present on the palm of the hand.

## INTRODUCTION

Because of its distinctive clinical picture, described in the previous chapter, smallpox has been recognized as a disease entity for many centuries. Its control by deliberate intervention, at first by variolation, then by vaccination, began long before such measures were adopted for any other disease. Likewise, knowledge of the virus that produced the disease and those that were used to control it, variola and cowpox or vaccinia viruses respectively, is as old as the relatively new science of virology. The particles that cause these two diseases were seen with the microscope, and then by electron microscopy, before any other viruses had been visualized, and their chemical composition was analysed earlier than that of any other animal virus. The family to which they belong, now called Poxviridae, was correctly categorized before any other viral family, and the genus *Orthopoxvirus*, whose members are the causative agents of smallpox, vaccinia and the several related

diseases with which this book is less directly concerned, was delineated as early as any other viral genus as the "variola-vaccinia subgroup" of the poxvirus group.

This chapter outlines the historical development and current state of knowledge of the orthopoxviruses, based primarily on studies with vaccinia virus. Much of the material presented will be of special interest to biologists, but it includes topics of greater complexity and of a more technical nature than can be readily understood by the otherwise informed general reader. However, the authors consider that it is important in this book to endeavour to embrace the full scope of currently available knowledge of the orthopoxviruses. For the virologist the account will appear unbalanced, since the intention is to limit it to providing the virological background that is necessary to understand how the body responds to infection with these viruses, how the clinical diagnosis can be confirmed by laboratory studies, and what other related agents may pose threats to man,

### The Nature of Viruses in General and Poxviruses in Particular

Viruses form a distinct group of agents, which differ fundamentally from cellular microorganisms. The infective particle, known as the virion, is inert; it proceeds to a dynamic phase only after it enters a susceptible cell and loses enough of its outer protective layers to allow its genetic material to be transcribed and translated. The inert poxvirion is the largest of all virions and its genetic material, a single molecule of double-stranded DNA, is among the largest of all viral genomes. Poxviruses differ from most other DNA viruses in that they replicate in the cytoplasm rather than in the nucleus of susceptible cells. To accomplish this, they have a battery of enzymes not found in other DNA viruses, including a viral DNA-dependent RNA polymerase which transcribes messenger RNA from the viral DNA.

confuse the diagnosis or give rise to problems in interpreting ecological data. To do this it will be necessary to describe some features of the orthopoxviruses, such as their structure, the composition of their genetic material and their behaviour in experimental animals, in some detail, but it is not necessary to provide a detailed analysis of the complex events of the replication cycle, a feature which has always been of central interest to virologists.

### CLASSIFICATION AND NOMENCLATURE

The internationally accepted classification of viruses is based primarily on the morphology of the viral particle (virion) and the nature and structure of the viral nucleic acid. As the largest of all viruses, the virions of poxviruses were the first to be seen with the microscope.

#### Development of Knowledge of the Structure of Poxvirions

As early as 1886, Buist (see Gordon, 1937) reported that he had seen what must have been the virions of vaccinia virus in stained smears, although he regarded them as spores. Calmette & Guérin (1901) used the rabbit to assay batches of vaccine lymph and in the course of this work they observed that the lymph contained numerous minute refractile particles which they suggested might be the "virulent elements". These observations were confirmed by Prowazek (1905), an expert microscopist, who found that they could be stained by Giemsa's method, and revived the

term "elementary bodies", originally introduced by Chaveau (1868) and used until recently to describe the virions. Paschen (1906) used a modified Loeffler's flagellar stain and championed the belief that the elementary bodies of vaccinia virus thus made visible with the microscope were the infective particles; they were later also called "Paschen bodies" in recognition of Paschen's extensive work in this field (Plate 2.1). Negri (1906) had shown that the infectivity of vaccine lymph would remain after the lymph had been passed through a filter that held back bacteria, but final proof that the elementary body was indeed the infectious entity was not provided until Ledingham (1931) showed that antisera produced against vaccinia or fowlpox viruses would simultaneously and specifically agglutinate the particles and neutralize the infectivity of the homologous but not the heterologous virus.

**Plate 2.1.** "Elementary bodies" (virions) of vaccinia virus. Bar = 1  $\mu$ m. Imprint of a rabbit cornea infected with vaccinia virus, prepared and stained by Paschen in 1906.

BY COURTESY OF S. DALES AND C.F. ROBINOW

Further analysis of the structure of poxvirions has depended on the use of the electron microscope with virions treated in various ways. Enzymatic digestion was used to demonstrate the existence of a substructure within the brick-shaped virions (Dawson & McFarlane, 1948). In a series of classical studies, Peters (1956), using enzymatic digestion with deoxyribonuclease and metal shadowing, demonstrated the major viral components and designated them as the outer membrane, the lateral bodies and the core. Thin sections of infected cells have been particularly valuable in elucidating the morphogenesis of the virions of vaccinia virus. Negative staining, combined with a variety of methods of degrading the virion, has been useful in analysing the substructure of vaccinia virions (Easterbrook, 1966; Medzon & Bauer, 1970) and in demonstrating the distinctive surface structure of the outer membrane. The negative staining method, first used for poxviruses by Nagington & Horne (1962), was the cornerstone of the laboratory diagnosis of smallpox as it was developed during the Intensified Smallpox Eradication Programme.

### The Nucleic Acid of Poxviruses

Following the development of methods of purification of vaccinia virus by differential centrifugation, workers at the Rockefeller Institute of Medical Research in New York showed that the virions contained 5.6% DNA (Hoagland et al., 1940) but no RNA (Smadel & Hoagland, 1942). The DNA was shown to be double-stranded, with a guanine + cytosine content of 36–37% (Jöklík, 1962), and subsequent studies showed that it occurred as a single linear molecule with a relative molecular mass of about 123 million comprising 186 000 base pairs (186 kbp).

### Classification of Poxviruses

Traditional classifications of diseases were based on symptoms, and certain diseases of man, cow, horse, sheep and pig were grouped together as "poxes" because they were characterized by pocks on the skin. Several of these diseases were caused by poxviruses, but the deficiencies of a classification of causative agents based on signs and symptoms were highlighted by the inclusion of chickenpox

(caused by a herpesvirus) and "the great pox" (syphilis—caused by a spirochaete) in the same category as smallpox.

By examining sections of poxvirus-infected tissues, pathologists came to recognize cytoplasmic inclusion bodies as characteristic of poxvirus infection (Guarnieri, 1892), although for many years they were regarded as protozoa. Gradually, however, the significance of the minute particles seen in stained smears was appreciated, and by the 1920s Aragão (1927) grouped together, as belonging to one family, the viruses of "myxoma, smallpox, molluscum contagiosum, epithelioma of fowls, etc.". Subsequently, Goodpasture (1933) formally proposed that vaccinia-variola, fowlpox, horsepox, sheep-pox, goat-pox, swinepox and molluscum contagiosum viruses should be grouped together as the genus *Borreliota*. Some years later, Buddingh (1953), using particle morphology and the character of the inclusion bodies as well as symptomatology and host range as the criteria, suggested a classification which, as far as it goes, accords with current ideas, except that all viruses with mammalian hosts were included in the same subgroup.

Writing on behalf of the Poxvirus Subcommittee set up by the Sixth International Congress for Microbiology, Fenner & Burnet (1957) produced a short description of the poxvirus group that has remained the basis of subsequent classifications in respect of the criteria used and the subdivisions adopted, although the names they proposed for species were not accepted, and the status of categories (genus, species, etc.) has been changed. With a view to bringing order and international agreement into viral classification and nomenclature, an International Committee on Nomenclature of Viruses was established in 1966, at the Ninth International Congress for Microbiology in Moscow. This Committee, whose name was subsequently changed to the International Committee on Taxonomy of Viruses, is now accepted as the international adjudicator on viral taxonomy and nomenclature (Matthews, 1983); the currently accepted classification of the poxviruses of vertebrates is set out in Table 2.1.

### Chordopoxvirinae: the Poxviruses of Vertebrates

The basic features of members of the subfamily Chordopoxvirinae are the large size

Table 2.1. The classification of poxviruses of vertebrates

Family	Poxviridae
Subfamily	Chordopoxvirinae
Genera	<i>Orthopoxvirus</i> (vaccinia)
(prototype species)	<i>Avipoxvirus</i> (fowlpox)
	<i>Capripoxvirus</i> (sheep-pox)
	<i>Leporipoxvirus</i> (myxoma)
	<i>Parapoxvirus</i> (milker's nodule)
	<i>Suipoxvirus</i> (swinepox)
	Unclassified molluscum contagiosum, tanapox

and characteristic ovoid or brick-like shape of the virion and the possession of a genome consisting of a single linear molecule of double-stranded DNA with a relative molecular mass that ranges, for different genera, between 85 million for *Parapoxvirus* and 185 million for *Avipoxvirus*. The virions of all members incorporate several enzymes, including a DNA-dependent RNA polymerase. These enable poxviruses to replicate in the cytoplasm of infected cells.

### The Genus *Orthopoxvirus*

The subfamily Chordopoxvirinae includes many viruses that are related to each other only in the general properties just listed. The genus with which this chapter is concerned, *Orthopoxvirus*, is much more homogeneous, as befits its lower taxonomic status. Table 2.2 lists the names, host ranges and geographical distribution of what, on the basis of their biological properties and genome structure, are 9 distinct species of *Orthopoxvirus*. All these species show extensive serological cross-reactivity, by both *in vitro* tests (gel diffusion, complement fixation, haemagglutination inhibition, etc.) and by neutralization tests

and cross-protection in laboratory animals; indeed the last two tests form the basis for the tentative allocation of a poxvirus isolate to the genus *Orthopoxvirus*.

Traditionally (e.g., Baxby, 1975, 1977b), species of *Orthopoxvirus* have been named primarily on the basis of the host animal from which they were derived, and identified on the basis of a range of biological characteristics in laboratory animals. The most important indicators were the host range, the morphology of the pock and the ceiling temperature at which it was produced on the chorioallantoic membrane of the developing chick embryo. The situation was changed by the discovery by Müller et al. (1978) and Esposito et al. (1978) that the DNAs of representative strains of each of several different species of *Orthopoxvirus* showed distinctive patterns after digestion with restriction endonucleases. With a larger number of strains of several different species, Mackett & Archard (1979) showed that all species of *Orthopoxvirus* shared a large conserved central part of their genomes. Analysis of the DNA structure now provides an alternative and more fundamental primary criterion for the classification of orthopoxviruses (see Fig. 2.6).

### Recognized Species of *Orthopoxvirus*

Historical features relating to the discovery and recognition of the accepted species of *Orthopoxvirus* are summarized below.

#### *Variola virus*

This virus, which caused human smallpox, has a restricted host range in laboratory

Table 2.2. Species of the genus *Orthopoxvirus*

Species	Animals found naturally infected	Host range in laboratory animals	Geographical range: natural infections
Variola	Man (infection now eradicated)	Narrow	Formerly world-wide
Vaccinia	Numerous: man, cow, <sup>2</sup> buffalo, <sup>2</sup> pig, <sup>2</sup> rabbit <sup>2</sup>	Broad	World-wide
Cowpox	Numerous: cow, man, rats, cats, gerbils, large felines, elephants, rhinoceroses, okapis	Broad	Europe (and Turkmenian SSR)
Monkeypox	Numerous: monkeys, great apes, anteaters, squirrels, man	Broad	Western and central Africa
Ectromelia	Mice, shrews	Narrow	Europe
Camelpox	Camels	Narrow	Africa and Asia
Taterapox	<i>Tatera kempi</i> (a gerbil)	Narrow	Western Africa
Raccoonpox	Raccoons	?Broad	USA
Uasin Gishu disease	Horses (from a wildlife reservoir host)	Medium	Eastern Africa

<sup>2</sup> Infected from man.

animals. Early reports of its transfer to animals are difficult to interpret, but monkeys were used quite early (Zuelzer, 1874) and extensively (e.g., Brinckerhoff & Tyzzer, 1906). Variola virus was subsequently grown in the rabbit cornea and a test developed to differentiate it from chickenpox virus (Paul, 1915). Later it was grown in chick embryos (Torres & Teixeira, 1935), and North et al. (1944) and Downie & Dumbell (1947b) showed that the pocks produced by variola virus on the chorioallantoic membrane were sufficiently distinctive to allow its differentiation from vaccinia and cowpox viruses. A detailed account of the virology of variola virus is presented later in this chapter.

### *Vaccinia virus*

Though a different species of *Orthopoxvirus* from Jenner's "variola vaccinae", vaccinia virus is the agent that has been most widely used for vaccination. Baxby (1977c, 1981) has summarized speculations about its origins (see Chapter 7). Many strains are supposed to have been derived from variola virus (Wokatsch, 1972; see Chapter 11). However, when experiments were carried out under conditions which precluded the possibility of cross-infection with vaccinia virus, "transformation" of variola virus into vaccinia virus could not be demonstrated (Herrlich et al., 1963).

There are many strains of vaccinia virus with different biological properties, although all have many features in common, such as their wide host range, rapid growth on the chorioallantoic membrane and distinctive genome maps. Since vaccinia virus has a broad host range and has been very widely used for many decades, accidental infections of domestic animals were not uncommon when human vaccination was practised on a large scale (see Table 2.7). Sometimes serial transmission occurs naturally in such animals (cows, buffaloes, rabbits).

In the history of smallpox eradication, vaccinia virus is second only to variola virus in its importance. It is also the "model" orthopoxvirus, with which the vast majority of laboratory investigations of viruses of this genus have been performed. Aspects of its virology are further discussed later in this chapter and its use in the prevention of smallpox is described at length in Chapters 6, 7 and 11.

### *Cowpox virus*

For many years before the time of Jenner, cowpox had been recognized as a disease of cows that was transmissible to man, producing ulcers on the cow's teats and on the milker's hands. The distinction between cowpox and vaccinia viruses was first made by Downie (Davies et al., 1938; Downie, 1939a,b). A number of strains of *Orthopoxvirus* recovered from diverse animals in zoos and circuses, as well as from rodents (see Chapter 29), have now been recognized as being very similar in both their biological properties and their genome maps to the strains of cowpox virus that have been recovered from cows and man; all of these strains belong to the cowpox virus species. Since cowpox virus was so important in the history of smallpox control (see Chapter 6) and causes occasional infections in man (see Chapter 29), its properties are discussed at greater length later in this chapter.

### *Monkeypox virus*

This virus was first recovered from cynomolgus monkeys that had been captured in Malaysia in 1958 and shipped by air to Copenhagen, where they were housed together for several weeks before the disease was recognized (Magnus et al., 1959; see Chapter 29). Several other isolations of the virus were subsequently made from captive primates in Europe and North America between 1960 and 1968 (Arita & Henderson, 1968). In 1970 monkeypox virus was isolated from a case of a disease in a human being in Zaire diagnosed clinically as smallpox (Ladnyj et al., 1972; Marennikova et al., 1972a); human monkeypox has now been recognized as a rare zoonosis occurring in several countries in western and central Africa.

Monkeypox virus infection in monkeys has been used as a model for the study of the pathogenesis of smallpox (see Chapter 3). The properties of monkeypox virus, the clinical and epidemiological features of human monkeypox, and its ecology in Africa are discussed in Chapter 29.

### *Ectromelia virus*

Infectious ectromelia, later called mousepox, was described in the United Kingdom by Marchal (1930), and the virus was subsequently recovered from laboratory mice in

many parts of the world (Fenner, 1982). Serological studies (Kaplan et al., 1980) suggest that voles may be a reservoir host of ectromelia virus in nature. Mousepox has been extensively used as a model system for studies relevant to the pathogenesis and immunology of smallpox (see Chapter 3). Ectromelia virus does not produce disease in man (Fenner, 1949a).

#### *Camelpox virus*

This virus shares several biological properties with variola virus and was originally described as being "extremely closely related" to variola virus (Baxby, 1972). However, it behaves differently in cultured cells (Baxby, 1974) and has a distinctive genome structure (Fig. 2.6). The camel appears to be the only natural host. It was first isolated in tissue culture by Ramyar & Hessami (1972) and its affinities with the genus *Orthopoxvirus* were recognized by Baxby (1972). Extensive studies in Somalia during the Intensified Smallpox Eradication Programme confirmed that it did not cause disease in man (Ježek et al., 1983).

#### *Taterapox virus*

This virus was recovered from pooled liver/spleen material obtained from small naked-soled gerbils (*Tatera kempi*) captured in Benin in 1964 (Kemp et al., 1974). It was studied by Gispén (1972) and Huq (1972), and characterized as a species of *Orthopoxvirus* by Lourie et al. (1975), who described it as "like variola minor virus" and speculated about its possible role in the long-term survival of variola virus. However, it has a distinctive genome map (see Fig. 2.6), which shows the usual features of orthopoxvirus DNA.

Nothing is known of its natural history, and little except what is shown in Table 2.3 is known of its biological properties. Taterapox virus may be one of several orthopoxviruses responsible for the high proportion of positive results obtained in orthopoxvirus haemagglutination-inhibition tests carried out on sera derived from a variety of wild animals captured in tropical rain forest regions in Africa (see Chapter 29).

#### *Raccoonpox virus*

The only indigenous orthopoxvirus yet recovered from the Americas, this virus was

isolated from raccoons in the eastern USA (Alexander et al., 1972) and characterized as a distinct species of *Orthopoxvirus* by Thomas et al. (1975). Its genome could not be mapped by methods used for other orthopoxviruses, since only about half the *HindIII* restriction endonuclease fragments cross-hybridized with those of other orthopoxviruses (Esposito & Knight, 1985), indicating a much more distant relationship than that found between other orthopoxviruses.

#### *Uasin Gishu disease virus*

This is an African orthopoxvirus recognized only by the fact that it causes papular lesions in horses in parts of Kenya (Kaminjolo et al., 1974a,b). It appears to be a virus enzootic in African wildlife, and if more widely distributed it could complicate ecological studies of monkeypox virus by blurring the serological picture.

### CHARACTERISTICS SHARED BY ALL SPECIES OF ORTHOPOXVIRUS

Having shown the way in which early studies of the morphology of poxvirus particles led to a classification of the family and the designation of the genus *Orthopoxvirus*, it is necessary now to outline current views on the structure and chemistry of these viruses. The vast majority of such studies were carried out with vaccinia virus, but they apply, with minor variations, to all orthopoxviruses.

#### Morphology of the Virion

Fig. 2.1, which is based on electron microscopic studies of vaccinia virus using thin sections, negative staining and freeze-etching, represents the virion as consisting of four major elements: core, lateral bodies, outer membrane and, as an inconstant component, an envelope. The well-defined central core (Plate 2.2C and D) contains the viral DNA, and on each side of the core there is an oval mass called the lateral body. The core and lateral bodies are enclosed within a well-defined "outer membrane", which has a characteristic ribbed surface structure (Plate 2.2A and Fig. 2.1), and is composed of a large number of surface tubules (Plate 2.3). The viral DNA within the core, which is associ-

Fig. 2.1. The structure of the vaccinia virion. Right-hand side, section of enveloped virion; left-hand side, surface structure of non-enveloped particle. The viral DNA and several proteins within the core are organized as a "nucleosome". The core has a 9-nm thick membrane, with a regular subunit structure. Within the virion, the core assumes a dumb-bell shape because of the large lateral bodies. The core and lateral bodies are enclosed in a protein shell about 12 nm thick—the outer membrane, the surface of which consists of irregularly arranged tubules, which in turn consist of small globular subunits. Virions released naturally from the cell are enclosed within an envelope which contains host cell lipids and several virus-specified polypeptides, including the haemagglutinin; they are infectious. Most virions remain cell-associated and are released by cellular disruption. These particles lack an envelope so that the outer membrane constitutes their surface; they also are infectious.

ated with at least 4 different proteins, is maintained in a superhelical configuration, and appears to occur in globular structures interconnected by DNA-protein fibres, resembling the nucleosome structures of eukaryotic chromatin (Soloski & Holowczak, 1981). Virions released spontaneously from cells are often enclosed within a lipoprotein envelope (Plate 2.2B) which contains the vaccinia haemagglutinin and several other virus-specific polypeptides (Payne & Norrby, 1976; Payne, 1978). Virions released by cellular disruption are infectious but lack an envelope (Appleyard et al., 1971); their outer surface is then composed of the outer membrane.

The envelope probably plays a role in the spread of virions within the animal body and thus in pathogenesis (see Chapter 3). More important in the context of smallpox control is the suggestion that the low protective power of inactivated vaccines (see Chapters 3

and 11) is due in part to the fact that they consist of inactivated non-enveloped virions (Boulter & Appleyard, 1973), whereas live virus vaccines produce envelope proteins in the process of replication.

### Antigenic Structure

The large and complex virions of orthopoxviruses contain a very large number of polypeptides, each of which probably contains several epitopes (antigenic sites). Much modern virological research is concerned with the structure and function of the viral polypeptides, their location in the virion and the processes by which they are produced during viral replication. Such research will undoubtedly illuminate our understanding of the biology of orthopoxviruses and the way in which they cause disease, but it is peripheral to the practical problems with which this book is concerned. However, three aspects of the composition of these polypeptides and their antigenic makeup are highly relevant: (1) some antigens show cross-reactivity across the whole subfamily Chordopoxvirinae; (2) many antigens, including those important in generating a protective immune response, show cross-reactivity within the genus *Orthopoxvirus*; and (3) some antigens are species-specific.

#### *Antigens common to the subfamily Chordopoxvirinae*

Investigations carried out some years ago using crude chemical and serological methods showed that one or several antigens were shared by all members of the subfamily that could be studied. Takahashi et al. (1959) demonstrated that both myxoma-immune sera and vaccinia-immune sera reacted with members of the *Orthopoxvirus*, *Leporipoxvirus*, and *Avipoxvirus* genera when tested by complement-fixation and immunofluorescence tests. Woodroffe & Fenner (1962) were able to demonstrate group cross-reactivity by complement-fixation or immunofluorescence tests only when they extracted the so-called "NP antigen" (Smadel et al., 1942) from myxoma or vaccinia virus. Such preparations reacted with antisera to a wide range of poxviruses, belonging to 5 different genera.

Ikuta et al. (1979) reinvestigated the problem, using radioimmunoprecipitation, and

**Plate 2.2.** Electron micrographs of vaccinia virions. **A:** Non-enveloped virion, showing the surface tubular elements that make up the outer membrane. **B:** Enveloped virion, as released from the infected cell and found in extracellular medium. **C:** Thin section of non-enveloped virion showing the biconcave core (c) and the two lateral bodies (lb). **D:** Viral core, released after treatment of virions with Nonidet 40 and mercaptoethanol. Bar = 100 nm. (**A** from Dales, 1963; **B** from Payne & Kristensson, 1979; **C** from Pogo & Dales, 1969; **D** from Easterbrook, 1966.)

demonstrated that among the 30 antigenic polypeptides found in one-dimensional gels prepared from cells infected with vaccinia, cowpox and Shope fibroma viruses (the last-named belonging to the genus *Leporipoxvirus*) there were 4 which showed cross-reactivity between the orthopoxviruses and Shope fibroma virus. There were, as expected, additional cross-reactive polypeptides shared by vaccinia and cowpox viruses but not found in fibroma virus.

These subfamily serological cross-reactions are not without practical importance. If methods that detect many different antigen-antibody reactions are used in serological surveys of animal sera for evidence of orthopoxvirus infection (e.g., immunofluorescence, enzyme-linked immunosorbent assay (ELISA), or radioimmunoassay), positive reactions may be produced by agents other than orthopoxviruses, such as tanapox virus, i.e., a positive result may mean only that the donor

of the serum has been infected with a member of the subfamily Chordopoxvirinae.

#### *Cross-reactions between orthopoxviruses*

An unknown agent having been identified as a poxvirus, perhaps by electron microscopy of infected tissues (see, for example, the work of Kaminjolo et al. (1974a) with the virus of Uasin Gishu disease), the next step in its identification as an orthopoxvirus depends on various kinds of serological cross-reactions between it and a recognized member of the genus, such as vaccinia virus. Three kinds of reactions are employed: (1) cross-protection in laboratory animals or cross-neutralization of infectivity; (2) demonstration of an orthopoxvirus-specific haemagglutinin; and (3) analysis of soluble antigens in agar gels by precipitation in gel, immunoelectrophoresis or radioimmunoprecipitation reactions. Both cross-protection and cross-neutralization are

strictly genus-specific, and orthopoxviruses are the only members of the family Poxviridae that produce a haemagglutinin.

**Cross-protection.** This is the classical way of demonstrating the relatedness of poxviruses as members of the same genus. It was first performed as a deliberate experiment by Jenner (1798), when he inoculated James Phipps with pus from a case of smallpox—2 months after having inoculated him with cowpox virus obtained from Sarah Nelmes. Cross-protection remains the most important test for membership of the genus *Orthopoxvirus*; it can now be supplemented by comparisons of DNA maps.

**Cross-neutralization of infectivity.** Cross-protection tests depend on a range of immune reactions, cell-mediated as well as humoral. A more limited but more flexible test, since it can be performed in eggs or cultured cells, is the neutralization of infectivity of the homologous and selected heterologous viruses by convalescent serum. This test has been widely used for demonstrating the relatedness of various orthopoxviruses (e.g., Downie & McCarthy, 1950; McNeill, 1968).

“Protective antigens”—i.e., those which elicit the production of neutralizing antibodies to orthopoxviruses—fall into two classes: the surface tubular elements of the outer membrane of the virion and some of the virus-specific antigens in the viral envelope. A protein with a relative molecular mass of 58 000 polymerizes to form the surface tubules that are a prominent feature of the outer membrane of vaccinia virions (Plate 2.2A). These surface tubular elements have been isolated from virions in a pure form (Plate 2.3); they elicit neutralizing antibody to non-enveloped but not to enveloped virions and block the neutralizing capacity of antibody to non-enveloped virions (Stern & Dales, 1976; Payne, 1980).

Other protective antigens are located in the viral envelope, which is found only in virions that are released naturally from cells. Analysis of the differences between the polypeptides of non-enveloped virions and enveloped virions by one-dimensional polyacrylamide gel electrophoresis (Payne, 1978) showed that the envelope contained 10 additional polypeptides (9 of which were glycosylated) with relative molecular masses of between 20 000 and 210 000.

Antibody to the isolated envelopes neutralized the infectivity of enveloped forms of

vaccinia virus, as demonstrated by the “anti-comet” test of Appleyard et al. (1971) (see Chapter 3, Plate 3.10), whereas antibody to inactivated non-enveloped virions did not do so (Payne, 1980). It is not known which of the envelope polypeptides are involved in neutralization reactions.

**Haemagglutination-inhibition tests.** Of all the poxviruses, only those of the genus *Orthopoxvirus* produce a haemagglutinin. This is active only on certain kinds of chicken cells (Nagler, 1942) and, with ectromelia virus, on mouse cells (Mills & Pratt, 1980). The agglutinability of chicken cells is genetically determined; White Leghorns produce agglutinable red blood cells whereas several other strains of chicken (e.g., Plymouth Rock) do not (Suzuki et al., 1955). It was the detection of haemagglutination that could be inhibited by vaccinia-immune serum that led Burnet & Boake (1946) to suggest that ectromelia virus was a member of the genus *Orthopoxvirus*. More recently, the production of the characteristic haemagglutination has been important in suggesting that raccoonpox virus (Thomas et al., 1975), taterapox virus (Lourie et al., 1975) and the virus of Uasin Gishu disease (Kaminjolo et al., 1974b) belong to this genus.

Early studies showed that vaccinia haemagglutinin was a lipoprotein, composed of a viral antigen and a lipid which was responsible for attachment to the red blood cell (Burnet, 1946; Stone, 1946; Chu, 1948). Active haemagglutinin can be reconstituted from these two components after they have been separated by ether/ethanol extraction (Smith et al., 1973). From the time of its discovery, the haemagglutinin was regarded as separable from the virus particle (Burnet & Stone, 1946) and this was the orthodox view for many years. However, the numerous investigations that demonstrated the dissociation of haemagglutinin and virion were carried out with preparations obtained by the disruption of infected cells. With the demonstration that vaccinia virions were sometimes released in an enveloped form, the problem was reinvestigated by Payne & Norrby (1976) and Payne (1979), who demonstrated that vaccinia haemagglutinin is the dominant glycoprotein in the envelopes of vaccinia virions and also occurs in the membranes of cells infected with vaccinia virus, where it can be demonstrated by haemadsorption tests. When cells are disrupted, the non-enveloped virions are readily separable from the haemagglutinin by centrifugation.

**Plate 2.3.** Purified surface tubules of the outer membrane of vaccinia virus. Bar = 100 nm. On the left is the upper part of an electropherogram of virion polypeptides run side by side with a preparation of the surface tubules that migrates as a single band of 58 K. (From Stern & Dales, 1976.)

Haemagglutinins of different species of *Orthopoxvirus* cross-react extensively. Using sera from immunized chickens, McCarthy & Helbert (1960) found no evidence of specificity for homologous antigens. On the other hand, Fenner (1949a) found that homologous titres were always higher than heterologous, when comparing vaccinia and ectromelia haemagglutinins. Infection with ectromelia virus of mice previously vaccinated with vaccinia virus resulted in a reversal of titres of inhibition of the respective haemagglutinins.

**Analysis of soluble antigens.** As already described, there are a few soluble antigens that show cross-reactivity throughout the subfamily Chordopoxvirinae. However, there are very many more that show cross-reactivity within each genus. The principal uses of methods of identifying soluble antigens (gel diffusion and radioimmunoprecipitation) are twofold: (1) in analysing the dynamics of viral replication and the detailed structure of the orthopoxvirion; and (2) in comparing different mutants, strains and species of *Orthopoxvirus*. In the present context, demonstration of extensive cross-reactivity between a known orthopoxvirus and a new poxvirus isolate would provide strong evidence that the latter belonged to this genus.

### Composition and Structure of the Viral DNA

The genome of all members of the genus *Orthopoxvirus* is a single linear molecule of double-stranded DNA, with relative molecular masses varying for different species from 110 million to 140 million, comprising between 165 kbp and 210 kbp. Orthopoxvirus DNAs contain no unusual bases and the guanine + cytosine content is very low—about 36%. The relative molecular mass of the DNA of different strains of vaccinia virus varies between 118 million and 125 million.

Vaccinia virus DNA behaves in an anomalous way when it is denatured. Instead of separating, the two sister strands form a large single-stranded circular molecule, being attached at or near each end of the genome by covalent links (Geshelin & Berns, 1974). For the most part the DNA sequences in the vaccinia genome are unique, but the two terminal fragments cross-hybridize with each other (Wittek et al., 1977) and with the termini of other species of orthopoxvirus (Mackett & Archard, 1979). This inverted terminal repetition is about 10 kbp long in the strains of vaccinia virus used by Wittek, but

Fig. 2.2. Schematic representation of the DNA of vaccinia virus (Lister strain). **A:** Linear double-stranded molecule with terminal hairpins and inverted repeats (not to scale). When denatured it forms a very large single-stranded circular molecule. **B:** Cleavage sites of restriction endonucleases *Hind*III (vertical lines) and *Sma*I (arrow). The asterisk indicates the fragment containing the thymidine kinase gene, which is used in experiments with vaccinia virus as a vector for hybrid vaccines. **C:** Each 10 kilobase pair (kbp) terminal portion includes 2 groups of tandem repeats of short sequences rich in adenine-thymine.

its length varies considerably in other orthopoxviruses. For example, in a series of mutants of cowpox virus studied by Archard et al. (1984), the length of the terminal repetition varied from 4.5 kbp to 41 kbp, almost 20% of the entire genome. Within each terminal repeat of vaccinia virus there are 30 reiterations of a 70-bp sequence arranged in tandem and grouped into 2 discrete groups of 17 and 13 units (Wittek & Moss, 1980; Fig. 2.2). Garon et al. (1978) visualized the terminal repetition by electron microscopy, which showed that the opposite ends of each strand are complementary to each other. The continuity of the DNA chain around the single-strand hairpin loop at the end of the molecule was shown in a variety of ways, culminating in the determination of the base sequence by Baroudy et al. (1982).

The analysis of vaccinia DNA and of the differences between DNAs derived from different species, strains and mutants of orthopoxviruses entered a new phase with Wittek's determination of a physical map of vaccinia virus DNA by analysis of the fragments produced when it was treated with various restriction endonucleases (Wittek et al., 1977).

Restriction endonuclease analysis provides a most important tool for the study of orthopoxviruses. On the one hand it opened the way to the cloning of selected fragments of orthopoxvirus DNA in *Escherichia coli*, ultimately encompassing the whole of the viral DNA, with all its implications for the examination of the molecular biology of viral replication. On the other hand, the demonstration by Mackett & Archard (1979) that a large central part of the genome of all

orthopoxviruses is very similar makes restriction endonuclease analysis a powerful method for taxonomic comparisons of different orthopoxviruses. In this book the composition of the DNA, as determined by restriction endonuclease analysis, has been accepted as the ultimate criterion for allocating viruses to species within the genus *Orthopoxvirus*, and as the technique of choice for examining the affinities of various strains and mutants that have been recovered from time to time.

### Non-genetic Reactivation

Poxviruses exhibit a unique kind of reactivation of "killed" virus. It was first observed by Berry & Dedrick (1936) with the leporipoxviruses myxoma virus and fibroma virus and was called viral "transformation". However, it is now known to be a general property of the poxviruses of vertebrates. Poxviruses that have been inactivated by methods which do not damage their DNA can be reactivated; any active member of the subfamily Chordopoxvirinae appears to be able to reactivate any other member of that subfamily inactivated by, for example, heating (review: Fenner, 1962). Reactivation depends on single cells being co-infected with the two viruses concerned, and is essentially an example of complementation. Heating destroys the core-associated DNA-dependent RNA polymerase; the active virus provides this enzyme, or enzymes that release DNA from the cores of both the active and the reactivated viruses. Non-genetic reactivation is a useful tool for obtaining hybrids between orthopoxviruses.

### Restriction Endonuclease Mapping of Orthopoxvirus DNAs

Restriction endonucleases are bacterial enzymes that cleave double-stranded DNA at sites which are determined by sequences of 4 or 6 nucleotides. To compare the DNAs of different orthopoxviruses, a few enzymes have been selected for which there are only a few cleavage sites along the whole length of the viral genome. After digestion, the mixture of DNA fragments is separated by electrophoresis in agarose gels, stained and photographed to show the bands of DNA arranged in accordance with their molecular weights. Cross-hybridization with selected radioactively labelled fragments of other orthopoxvirus DNAs makes it possible to identify relationships between different orthopoxviruses and arrange the fragments in a linear order along the viral genome (see Fig. 2.6).

To simplify comparisons between the maps of different orthopoxvirus species, strains and mutants, a method of computer-aided analysis of the cleavage sites described by Gibbs & Fenner (1984) has been used. Briefly, the maps of different DNAs are aligned along selected highly conserved cleavage sites. All other cleavage sites for particular enzymes, on all the DNAs under study, are then compared and scored as present, absent, or "impossible" (the DNA molecule may be too small to accommodate the cleavage site in question). The figures thus obtained are analysed by the computer program MULCLAS (Lance & Williams, 1967) and the results expressed as a dendrogram indicating degrees of dissimilarity. The absolute values depend on the number of attributes (separate cleavage sites) in the group of DNAs under study, so that different dendrograms may give quite different figures for the "index of dissimilarity" between the same DNA molecules, if different restriction enzymes or groups of enzymes are used. With orthopoxvirus DNAs such analysis may place undue weight on the effects of internal deletions and transpositions, but it offers a rough method of comparing strains that is better than visual comparisons of the DNA maps (see Fig. 2.7).

More detailed analysis of the orthopoxvirus DNA is carried out by incorporating selected fragments into plasmids and then into *Escherichia coli*. Large quantities of the selected fragments can then be produced and analysed by further digestion with restriction endonucleases for which there are numerous cleavage sites, or particular pieces of DNA can be sequenced.

### CHARACTERIZATION OF ORTHOPOXVIRUSES BY BIOLOGICAL TESTS

Morphology is useful for classification only at the subfamily level, since only the genus *Parapoxvirus* can be unequivocally distinguished from the other genera of Chordopoxvirinae by the morphology of the virions, as seen in negatively stained preparations. Cross-protection and neutralization tests make it possible to allocate a poxvirus to the genus *Orthopoxvirus*. Allocation of an orthopoxvirus to a particular species depends on the use of several biological and chemical tests, respectively to categorize the effects of the virus in various animals and cell systems and to define the nature of its DNA and polypeptides.

In this book attention will be concentrated on the attributes of the 4 orthopoxviruses that were of most significance in relation to

smallpox and its eradication: variola, vaccinia, cowpox and monkeypox viruses. More detailed descriptions of the biology of these viruses, and that of the other species of *Orthopoxvirus*, can be found in Fenner et al. (1987).

### Lesions in Rabbit Skin

Historically, one of the earliest tests which clearly differentiated variola from vaccinia virus was the demonstration that only the latter virus produced lesions in rabbit skin, after either scarification or intradermal inoculation. Subsequent investigations have confirmed the value of this test.

Within the *Orthopoxvirus* genus, there is a correlation between the reaction in rabbit skin (Plate 2.6) and the character of the pocks produced on the chorioallantoic (CA) mem-

c. 1965

**Plate 2.4.** Allan Watt Downie (b. 1901). Formerly Professor of Bacteriology in the University of Liverpool, Downie was a leading worker in the virology and immunology of poxviruses from the late 1930s until the 1970s and made major contributions to our knowledge of cowpox, variola and tanapox viruses. K.R. Dumbell (Plate 2.12) and H.S. Bedson (Plate 2.14) trained under him as graduate students.

brane (see below). Each of 3 species (cowpox, monkeypox and neurovaccinia, including rabbitpox virus) which produce haemorrhagic (ulcerated) pocks on the CA membrane cause large indurated skin lesions with a purple-coloured central area that usually ulcerates before healing. "Dermal" strains of vaccinia virus, which produce small white pocks on the CA membrane, and white pock mutants of cowpox, monkeypox and rabbitpox viruses elicit smaller, pink, nodular lesions. Variola, camelpox and ectromelia viruses produce at most a small papule with transient erythema, which is non-transmissible.

### Pocks on the Chorioallantoic Membrane

All orthopoxviruses produce pocks on the CA membrane, without the need for adaptation by passage. Goodpasture et al. (1932) first cultivated vaccinia virus on the CA membrane and Keogh (1936) demonstrated that dermal and neurotropic strains of vaccinia virus produced readily distinguishable kinds of pocks, which were white and haemorrhagic (ulcerated) respectively. In contrast, variola virus produces small white pocks on the CA membrane, which can be readily distinguished from those of vaccinia virus (North et al., 1944). Cowpox virus was first cultivated

on the CA membrane by Downie (1939a), who showed that it produced bright-red haemorrhagic pocks, clearly distinguishable from those of both vaccinia and variola viruses (Plate 2.5).

Monkeypox virus was not recognized until 1958, when Magnus et al. (1959) demonstrated pocks, which "resembled closely those described for variola virus", on CA membranes inoculated with material from pustular lesions on infected monkeys. Later studies (Marennikova et al., 1971; Randle & Sayeed, 1972) showed that the pocks of monkeypox virus are distinguishable from those of other orthopoxviruses; like those of variola virus, they are small, but instead of being dense, white and opaque, they are pink and have an ulcerated, slightly haemorrhagic surface.

The pocks produced by species that elicit opaque white pocks on the CA membrane are usually uniform in character; all pocks on a membrane are similar. On the other hand, species or strains of virus that produce ulcerated pocks (cowpox, monkeypox, and the neurovaccinia and rabbitpox strains of vaccinia virus) regularly produce white pock mutants (Downie & Haddock, 1952; Fenner, 1958; Gemmell & Fenner, 1960; Dumbell & Archard, 1980), which usually differ from the strains producing red pocks in several other biological characteristics, such as the type of lesion in the rabbit skin and, often, their lethality for mice and chick embryos. Vaccinia virus passaged for commercial vaccine production may contain virions producing both white and grey ulcerated pocks; the passage of vaccinia virus by intracerebral or intratesticular inoculation of rabbits or mice usually selects for mutants which produce ulcerated, haemorrhagic pocks on the CA membrane.

### Ceiling Temperature

When carrying out experiments on the growth of several different viruses on the CA membrane, Burnet (1936) noticed that ectromelia virus produced pocks at 37 °C but not at 39.5 °C. This finding was developed by Bedson & Dumbell (1961), who introduced the concept of the "ceiling temperature" as the highest temperature at which pock formation on the CA membrane would occur. The ceiling temperature has proved to be a useful criterion for distinguishing between different species of *Orthopoxvirus* (Table 2.3). It has also

### Appearance of Orthopoxvirus Pocks on the Chorioallantoic Membrane

The most useful laboratory test for distinguishing between species of *Orthopoxvirus* is the appearance of pocks on the CA membrane. Unlike plaques in cultured cells, which result from the direct interaction between cells and virus, a third component enters into the appearance of pocks—namely, leukocytes and erythrocytes delivered to the site via the bloodstream. Basically, a pock is a greyish-white focus, varying in diameter from 0.4 mm to 4 mm, according to virus species. It is produced by a combination of hyperplasia of the ectodermal layer of the CA membrane and the infiltration of cells into the mesodermal layer. Sometimes, as with variola virus, the surface of the pock is glossy white, owing to pronounced hyperplasia of the ectoderm; sometimes, as with monkeypox virus, the superficial layer ulcerates and there is a superficial haemorrhage into the crater. The pocks of cowpox virus are bright red, because very little leukocytic infiltration occurs and there are capillary haemorrhages into the pock.

Expression of the "characteristic" pock phenotype is influenced by the concentration of pocks and the temperature of incubation. Expression of the "red" pock phenotype is enhanced when the pocks are semiconfluent or confluent. Also, at higher temperatures pocks tend to be greyish-white and non-ulcerated, whereas at lower temperatures some species (but not variola virus) produce pocks with an ulcerated, haemorrhagic centre. For example, at 37 °C camelpox virus produces small pocks very similar to those of variola virus (Mayr et al., 1972), but at 35 °C it produces pocks with a haemorrhagic centre (Marennikova et al., 1973). Likewise, at 37 °C monkeypox virus produces white pocks very like those of variola virus (Magnus et al., 1959), whereas at 35 °C the pocks are ulcerated and haemorrhagic (Marennikova et al., 1971).

proved useful in distinguishing between variola major and alastrim viruses (Nizamuddin & Dumbell, 1961; Dumbell & Huq, 1986). Cultured cells can also be used for measuring ceiling temperatures (Porterfield & Allison, 1960).

Different species of orthopoxviruses recovered from geographically separate places and at different times usually have the ceiling temperature characteristic of the species. However, in the laboratory ceiling temperature mutants, which are then usually called temperature-sensitive (*ts*) mutants, can be readily obtained by appropriate selection methods. Sambrook et al. (1966) and Dales et al. (1978) have recovered large numbers of different *ts* mutants of vaccinia virus. Conversely, Dumbell et al. (1967) obtained two thermo-efficient strains of variola major virus by serial passage at incrementally higher temperatures.

### Lethality for Mice and Chick Embryos

The response to infection depends on the age of the animal and its genetic background, the route of inoculation, and the viral species

or strain. Variola virus is much less lethal for mice and chick embryos than the other species of *Orthopoxvirus* that can infect man (Table 2.3).

### Growth in Cultured Cells

Most orthopoxviruses can be grown in one or another kind of cultured cell and assayed by plaque counts in suitable susceptible cells. Species which have a wide host range among intact animals (e.g., vaccinia, cowpox and monkeypox viruses) tend to grow to high titres and in a wide range of cells, and to produce lytic plaques. Species with a restricted host range, such as variola virus, replicate in a narrower range of cells and often produce hyperplastic foci (see Plate 2.13). However, on serial passage, adaptation occurs readily and may involve change to a more lytic plaque. Monolayers infected with viruses that produce hyperplastic foci usually yield much less virus than those infected with viruses that produce lytic plaques, since most cells in the monolayer remain uninfected. Differential growth capacity in particular cell lines (e.g., the rabbit cell line RK 13 and pig embryo

**Plate 2.5.** The appearance of pocks on the chorioallantoic membrane produced by various species of *Orthopoxvirus* that infect man. Monkeypox virus pocks photographed after incubation for 3 days at 35 °C; all others after 3 days at 36 °C. **A:** Variola major virus. **B:** Vaccinia virus (Lister strain). **C:** Monkeypox virus (Copenhagen strain). **D:** Cowpox virus (Brighton strain).

**Plate 2.6.** Lesions produced in the rabbit skin 5 days after the intradermal inoculation of doses of  $10^5$  pock-forming units of various species of *Orthopoxvirus*. Ectromelia (ECT), taterapox (TAT) and camelpox (CAM) viruses produce no lesions and variola (VAR) virus elicits only a slight erythema. Monkeypox (MPX) and cowpox (CPX) viruses produce large indurated lesions with a purple centre that often ulcerates. The response to vaccinia virus (VAC) varies with the strain; "dermal" strains usually produce a distinct red indurated nodule and neurovaccinia a lesion like that produced by cowpox virus.

**Plate 2.7.** Cytoplasmic inclusion bodies in cells infected with orthopoxviruses. **A:** B-type inclusion bodies (Guarnieri bodies) in hyperplastic ectodermal cells of the chorioallantoic membrane, in a pock produced by variola virus. Note that the surface of the pock is intact and there are no erythrocytes in the ectoderm, although they are present within a vessel in the mesoderm. (Eosin and methyl blue stain.) **B:** B-type (pale-red, irregular) and A-type (large eosinophilic, with halo) inclusion bodies in ectodermal cells of the chorioallantoic membrane, in a pock produced by cowpox virus. There are also a number of nucleated erythrocytes in the ectoderm and free in the mesoderm, and the surface of the pock is ulcerated. **C:** Section of the skin of a patient with haemorrhagic-type smallpox, showing Guarnieri bodies, and free erythrocytes below an early vesicle. (Haematoxylin and eosin.)

A. W. DOWNIE

kidney cells) may be useful in distinguishing between variola and monkeypox viruses when these viruses are first inoculated into such cells (see below); however, adaptation occurs readily.

Since the viral haemagglutinin is inserted into the cytoplasmic membrane of infected cells, haemadsorption can be used to detect orthopoxvirus infection in cultured cells. Different patterns of haemadsorption have proved useful in distinguishing between isolates of variola virus from different parts of the world (see below).

### **Inclusion Bodies**

Two kinds of inclusion bodies occur in the cytoplasm of cells infected with orthopoxviruses, which Japanese investigators (Kato et al., 1959) have distinguished as A-type and B-type (Plate 2.7). B-type inclusions are the sites of viral replication and are produced by all orthopoxviruses. A-type inclusions are strongly eosinophilic and are found only in cells infected with cowpox, ectromelia and raccoonpox viruses.

### **Comparison of Biological Characteristics of Different Species**

Although a good deal of variation in biological behaviour occurs between different strains of the orthopoxviruses that have been the most carefully studied, certain characteristics appear to be regularly associated with each species (Table 2.3). Most of the characteristics listed are usually or invariably found with recently isolated strains of all species; some appear to be very stable, whereas others can be altered by the deliberate selection of mutants or by serial passage at high concentration.

## **VIRAL REPLICATION**

Viral replication is a central focus of virology, yet it is largely peripheral to the understanding of smallpox and vaccination, with which this book is concerned. We shall therefore restrict the description of the replication of poxviruses to a simplified diagram (Fig. 2.3), and describe briefly aspects that are relevant to the pathogenesis and immunology of smallpox and vaccinia—namely, the initia-

tion of infection, assembly and release of progeny virions and changes in infected cells. The reader interested in a more detailed account of poxvirus replication should consult Moss (1985) or Fenner et al. (1987).

### **Adsorption, Penetration and Uncoating**

The first stage of viral infection consists of adsorption to and penetration of host cells. Enveloped and "naked" orthopoxvirus particles, although both infectious, behave differently. The outer membrane of the non-enveloped particle fuses with the plasma membrane at the surface of the cell, or within a vacuole formed by invagination of the plasma membrane, thus releasing the viral core into the cytoplasm. Enveloped virions are adsorbed more rapidly and efficiently, which explains why they play an important role in the spread of infection, both in cultured cells and in intact animals (see Chapter 3).

### **Assembly and Maturation**

Electron microscopic analysis of thin sections of infected cells suggest a sequence of developmental events, shown diagrammatically in Fig. 2.4. The initial stages of virion formation occur in circumscribed granular electron-dense areas of the cytoplasm. The first morphologically distinct structures are crescents (or cupules in three dimensions) consisting of a bilayer membrane with a brush-like border of spicules on the convex surface and granular material adjacent to the concave surface (Plate 2.8). The spicules are thought to give the membrane its rigid convex shape, which determines the size of the immature viral particles. Ultimately the spicules appear to be replaced by the surface tubular elements of the outer membrane. The immature viral membranes appear circular (or spherical in three dimensions) with a dense nucleoprotein mass embedded in a granular matrix. The nucleoprotein appears to enter the immature envelopes just before they are completely sealed. It is unclear whether the majority of the proteins destined to form the mature particle, which includes proteins of the core membrane and the lateral bodies and many viral enzymes, are enclosed within the membrane of the immature particle or injected simultaneously or sequentially after its

Table 2.3. Biological characteristics of recognized species of *Orthopoxvirus*

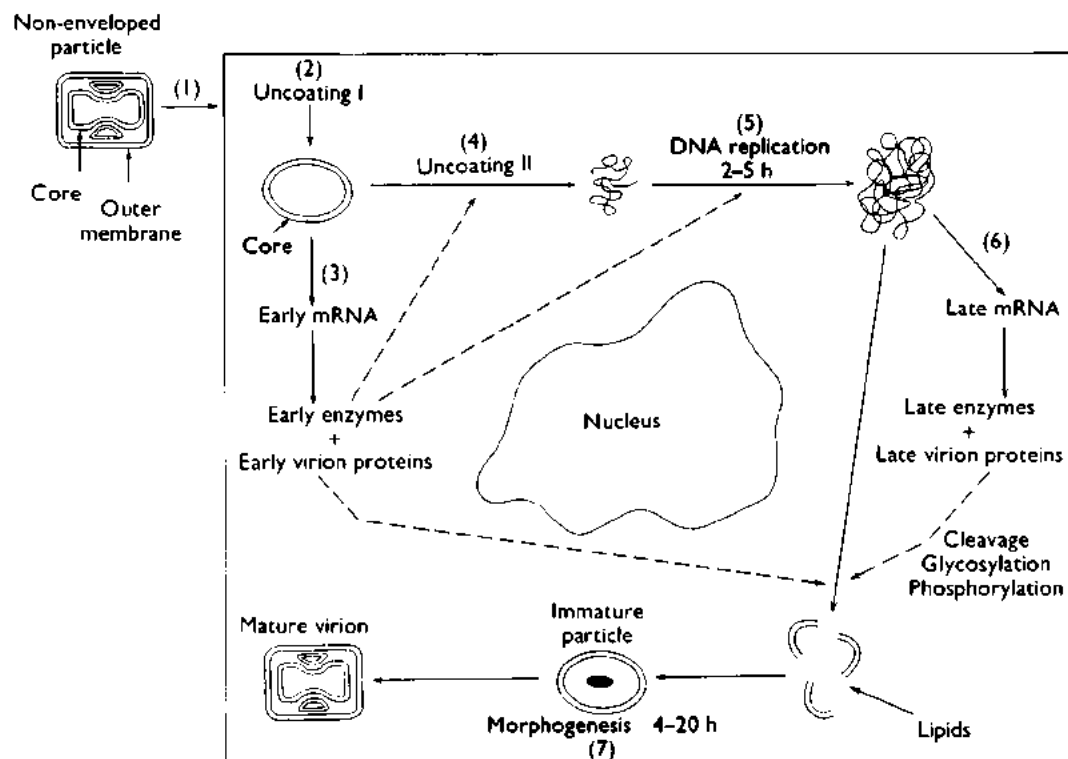

Fig. 2.3. The replication cycle of vaccinia virus. Both enveloped and non-enveloped particles are infectious but differ in their attachment to cells and mode of entry (not shown). The sequence of events is (1) attachment and entry. (2) uncoating I, whereby the outer membrane is removed by cellular enzymes, leaving the core, (3) immediate early transcription from DNA within the core by the viral transcriptase, leading to the production of early enzymes which include the enzyme that produces (4) uncoating II and release of the viral DNA into the cytoplasm. Early transcription continues and simultaneously (5) DNA replication occurs, after which (6) late transcription occurs from the newly synthesized DNA, followed by translation, and cleavage, glycosylation and phosphorylation of some of the late proteins. Morphogenesis (7) is illustrated in more detail in Fig. 2.4. (From Moss, 1985.)

development. The additional morphological changes by which the immature particle is reorganized to become a mature virion require continuing protein synthesis. Although DNA replication does not involve the activity of the cell nucleus, assembly is very inefficient in cells lacking functional nuclei.

### Release

In the majority of the vaccinia-virus/cell systems that have been studied, most of the mature progeny virions remain cell-associated. Cell-associated virions are released when the cell undergoes necrosis, and they may infect contiguous cells, within a solid organ or in a cell monolayer, without ever being exposed to an extracellular environment. This occurs by the recruitment of contiguous cells into polykaryocytes (Dales & Siminovich,

1961), as well as by the necrosis of the infected cell, and is well demonstrated by the development of plaques in the presence of neutralizing antibody in the overlay medium (see Chapter 3, Plate 3.10).

Release of virions from the plasma membrane of the intact cultured cell also occurs. Tsutsui (1983) observed a simple budding process in FL cells, but more commonly mature "naked" virions acquire a double membrane envelope in the vicinity of the Golgi apparatus (Ichihashi et al., 1971; Payne & Kristensson, 1979; Plate 2.9A) and migrate to the cell surface, apparently under the influence of cytoplasmic microfilaments (Hiller et al., 1979). At the cell surface the outer of these two membranes fuses with the plasma membrane, releasing enveloped virions (Plate 2.9C and D). This process also occurs in mice infected with vaccinia virus (Payne & Kristensson, 1985).

Fig. 2.4. Diagram of a cell representing the morphogenesis of vaccinia virions. The viroplasm, or viral "factory", visualized in stained cells as the B-type inclusion body, is first seen at 2.5 hours, cupules first appear at 4 hours, and some are completed as immature particles at 6–8 hours. From 8 hours onwards mature particles appear, maturation occurring within the membrane of the immature particles, which loses its spicules and acquires surface tubules. Processes involving envelopment and release are not shown. (From Moss, 1985.)

The efficiency of egress by envelopment is affected both by the type of host cell and by the strain of virus used; RK 13 cells give a high yield of enveloped virions, especially with certain strains of vaccinia virus (Payne, 1980). Routine electron microscopy of material from smallpox pustules and scabs rarely revealed enveloped virions (J. H. Nakano, personal communication, 1982). In cells infected with cowpox virus, most mature virions are usually associated with A-type inclusion bodies (see Plate 2.10).

### Cellular Changes

Within one or two hours of infection, so-called "toxic" changes may occur in the infected cells, which in monolayer cultures become rounded and retract from each other (Fig. 2.5). New antigens occur on the cytoplasmic membrane very early (Ueda et al., 1972), and by the 4th hour there is cytological evidence of viral replication; basophilic areas appear in the cytoplasm—the viral "factories" of Cairns (1960). Eventually gross changes

occur in the cells; depending on the particular virus–host cell combination there may be an aggregation of cells into hyperplastic foci, adjacent cells may fuse to form large polykaryocytes, or cell necrosis and rupture may occur, with release of the cell-associated virions.

### Inclusion bodies

The appearances of the inclusion bodies found in orthopoxvirus-infected cells is shown in Plate 2.7. B-type inclusion bodies are irregular in shape, stain rather weakly with most histological stains and are found in all poxvirus-infected cells. They were first described in cells infected with variola and vaccinia viruses by Guarnieri (1892) and are often eponymously known as "Guarnieri bodies". It is now clear that these B-type inclusions are the cellular sites of poxvirus replication. A-type inclusion bodies, on the other hand, are usually spherical, stain brilliantly with eosin, and are characteristic of cells infected with ectromelia, cowpox and raccoonpox viruses but are not found in infection with the other orthopoxviruses. Depending on the genetic nature of the virus, A-type inclusions may contain many mature virions or be devoid of them (Plate 2.10; Ichihashi & Matsumoto, 1968). They usually appear late in infection and are not associated with viral replication.

### Changes in the cell surface

Some of the earliest changes, and the most significant in relation to the immune response, are the virus-induced alterations in the plasma membranes of infected cells. Some virus-coded antigens are expressed on the surface of the cell within 2 hours of infection (Ueda et al., 1972; Amano et al., 1979); other polypeptides which develop late in infection, including the haemagglutinin and several other envelope glycoproteins, are also incorporated into the plasma membranes of infected cells (Payne, 1979). The development of membrane-associated haemagglutinin can be followed by haemadsorption tests, which have been used in the analysis of differences between variola major and alastrim viruses (Dumbell & Wells, 1982; Dumbell & Huq, 1986; see Table 2.4). Some of these viral antigens promote cell fusion and thus cell-to-cell spread of virions.

**Plate 2.8.** Viral morphogenesis. **A:** Infected cell showing viral "factory" area with immature particles on right; mature naked intracellular virions on left. Bar = 1000 nm. **B:** "Factory" area showing the "caps" (cupules) of developing immature viral particles. Bar = 100 nm. (**A** from Payne & Kristensson, 1979; **B** from Dales & Siminovich, 1961.)

### CHARACTERIZATION OF ORTHOPOXVIRUSES BY CHEMICAL METHODS

Species, strains, and mutants of orthopoxviruses can be characterized by analyses of their DNAs, using restriction endonuclease digestion, or by an examination of gene products (polypeptides) applying serological tests or separation in polyacrylamide gels.

#### Comparison of Viral DNAs

##### *Differences in DNAs of different species*

The DNAs of orthopoxviruses range in size from 165 kbp for variola virus to 210 kbp for cowpox virus. The larger differences, i.e., between species, are reproducible but there is some strain variation within each species. As will be described later, deletion mutants occur quite commonly and often involve the loss of substantial fragments of DNA from one or the other end of the genome.

As illustrated in Fig. 2.2, the opposing terminal fragments of the DNAs of most orthopoxviruses contain long terminal repeats, hence they cross-hybridize. Variola virus is an exception, in that it lacks an obvious inverted terminal repeat, so that opposite termini do not cross-hybridize (Mackett & Archard, 1979; Dumbell & Archard, 1980). One end of variola DNA was found to hybridize with termini of the DNAs of other species of orthopoxviruses; the other end hybridized with a subterminal fragment of monkeypox DNA. The absence of a terminal repeat is not absolute; Esposito & Knight (1985) have shown that a very small fragment from the vaccinia DNA terminus that hybridizes well with one end of variola DNA hybridizes weakly with the other end, suggesting that there is a very small terminal repetition, less than 0.5 kbp, in variola DNA.

Major comparative studies of the DNAs of different species of orthopoxviruses have been carried out by Mackett (1981) in the United Kingdom and Esposito in the USA

**Plate 2.9.** Release of enveloped virions by cells of mouse respiratory tract after infection with vaccinia virus. **A:** Acquisition of double membranes in vicinity of Golgi apparatus. **B:** Double-enveloped particles in cytoplasm of cell. **C** and **D:** Virions with a single envelope after release from cells. bars = 500 nm. (From Payne & Kristensson, 1985.)

(Esposito & Knight, 1985). In this section an attempt is made, using restriction endonuclease maps, to provide the chemical basis for the species designations that are shown in Tables 2.2 and 2.3.

Fig. 2.6 sets out the cleavage sites of the restriction endonuclease *Hind*III in the DNA molecules of strains of each of the 8 species of *Orthopoxvirus* for which such maps are available. Uasin Gishu disease virus DNA has not yet been analysed by restriction endonuclease digestion. Several *Hind*III fragments of raccoonpox virus DNA (the only species of *Orthopoxvirus* yet found to be endemic in the

Americas) cross-hybridize with those of other *Orthopoxvirus* species, but not at all with *Hind*III fragments of DNAs of mammalian poxviruses of other genera (*Leporipoxvirus*, *Parapoxvirus*) found in North America. However, the "map" of raccoonpox virus does not lend itself to comparisons by the computer program used for producing Fig. 2.7. The large central conserved area of all the DNAs that have been mapped is readily apparent in the *Hind*III maps. The close resemblance between the representative strains of particular species (shown in greater detail in Fig. 2.9 and 2.10, and Chapter 29, Fig. 29.1 and 29.4)

Fig. 2.5. Cellular changes seen at various times (logarithmic scale) after infection of a monolayer of cultured cells.

and the differences between species, particularly towards the ends of the molecule, are apparent, but it is difficult to appreciate these quantitatively by visual inspection of restriction maps. The similarities and differences are brought out better by the dendrogram (Fig. 2.7). On the basis of this kind of analysis it is possible to distinguish clearly between all species of *Orthopoxvirus* that have been mapped. Other analyses, involving several strains of each of several species in a single dendrogram (Fenner et al., WHO/SE/80.154), showed that all strains of each species clustered together and species remained clearly separable.

#### *Changes in DNA associated with mutation and recombination*

The foregoing description of the structure and composition of orthopoxvirus DNA may have given the impression that the DNAs of various species are fixed. To some extent this is true; however, minor changes due to mutation occur very frequently and deletion mutations, which are known to occur commonly among the orthopoxviruses with a wide host range (vaccinia, cowpox and monkeypox viruses), can be associated with losses of substantial amounts of viral DNA. Furthermore, different strains and species of *Orthopoxvirus* recombine readily when single cells are subjected to mixed infection, with associated changes in the DNA.

Diversity in DNA molecules may be readily generated within a species, presumably by "autorecombination" during replication. For example, the terminal fragments of vaccinia DNA may become heterogeneous in length

(Wittek et al., 1978), as does the internal junction fragment of white pox mutants of cowpox virus (Archard et al., 1984). These heterogeneities can be eliminated, at least temporarily, by cloning the virus. Indeed, cloning, by the growth of stocks from single pocks or plaques, is an obligatory procedure if stocks of relative genetic homogeneity are required. For example, both Fenner (1958) and Ghendon & Chernos (1964) found that stock preparations of several different strains of smallpox vaccine contained virus that produced mixed pocks (ulcerated and non-ulcerated), which could be separated by cloning.

The most important kind of mutation, from the point of view of the global smallpox eradication campaign, were the white pox mutants of monkeypox virus (see Chapter 30). All orthopoxviruses that produce ulcerated (haemorrhagic) pocks on the CA membrane (cowpox, monkeypox and neurovaccinia strains of vaccinia virus, including rabbitpox virus) produce non-ulcerated (white) pocks with a frequency (from cloned preparations) that varies between 0.1% and 0.01%. In all cases in which several white pocks have been examined, most mutants obtained from a single cloned preparation have been different (Gemmell & Fenner, 1960; Dumbell & Archard, 1980), and the majority of such mutants involve large deletions from one or the other end of the genome, which are often associated with transpositions (Archard et al., 1984; Moyer & Rothe, 1980; Dumbell & Archard, 1980). In spite of these major changes in the amount of DNA, the rest of the genome map is recognizably that of the parental virus (see Chapter 30, Fig. 30.2).

**Plate 2.10.** A-type inclusion bodies produced by cowpox virus. Depending on the genetic characteristics of the strain, the inclusion body may contain large numbers of virions (A), or none at all (B).

### Comparison of Viral Polypeptides

#### *Serological tests*

The earliest methods of comparing the polypeptides of different orthopoxviruses were based on serological tests. All orthopoxviruses show substantial cross-reactivity in tests for neutralization of infectivity, although differences between species and

strains can be demonstrated by absorption tests (Baxby, 1982a). Gel-diffusion tests, which had been shown to distinguish over 20 different antigens in cells infected with rabbitpox virus (Appleyard & Westwood, 1964a), provided an obvious method for attempting the serological differentiation of different species of *Orthopoxvirus*. Using absorbed sera, Gispén & Brand-Saathof (1974) and subsequently Esposito et al. (1977a)

Fig. 2.6. Physical map locations of *Hind*III restriction sites in the DNAs of 8 of the recognized species of *Orthopoxvirus*. Origin of DNAs: Monkeypox (Zaire)—Congo 1970, an isolate from a human case in Zaire; Monkeypox (W. Africa)—Copenhagen, an isolate from monkey, probably originating in West Africa; Taterapox—Benin isolate; Ectromelia—Hampstead strain; Raccoonpox—isolate from Maryland; Cowpox—Brighton strain; Camelpox—Somalia 1248; Variola major—Harvey strain; Alastrim—Butler strain; Vaccinia—Lister and Venezuela strains. (Data from Esposito & Knight, 1985.)

Fig. 2.7. Dendrogram illustrating the similarities and differences between the DNAs for which restriction sites are shown in Fig. 2.6 (except for raccoonpox DNA). Presence, absence or impossibility of sites (because the DNA molecules were too small) were analysed as described by Gibbs & Fenner (1984) using the squared Euclidean metric (number of attributes = 45). The "index of dissimilarity" has no absolute value, but the dendrogram shows that pairs of viruses of the same species (variola, monkeypox and vaccinia) resemble each other more than any other species. Such comparisons are developed with larger numbers of strains of various orthopoxviruses in Fig. 2.9 (variola virus), Fig. 2.10 (vaccinia virus), and in Chapter 29, Fig. 29.1 (monkeypox virus) and Fig. 29.4 (cowpox virus).

demonstrated species-specific antigenic patterns for variola, vaccinia and monkeypox viruses. Maltseva & Marennikova (1976) used absorption in the test well of gel-diffusion plates to distinguish between variola, mon-

keypox, vaccinia and cowpox viruses and showed that isolates from a number of different animals in outbreaks in zoos (okapis, elephants, and various carnivores) reacted like cowpox virus.

Immunofluorescence (Gispen et al., 1974), radioimmunoassay (Hutchinson et al., 1977) and ELISA (Marennikova et al., 1981) have also been used for differentiating variola, monkeypox- and vaccinia-specific antisera, after absorption of the tested sera with homologous and heterologous antigens. All methods were effective in allowing specific diagnoses of monkeypox infection to be made with certain monkey sera. However, while absorption tests are usually successful in demonstrating specific antibodies in high-titre sera, they fail with sera of low titre, such as are often found in sero-epidemiological surveys. Further, sensitive tests such as radioimmunoassay-absorption require antisera to the gamma-globulins of the species under test; such antisera are available for monkeys but not for most other species of wild animal. Thus these tests are unsuitable for routine use with sera from a range of different animals, such as are usually collected during ecological surveys.

*Comparisons of polypeptides in one-dimensional polyacrylamide gels*

Virion polypeptides (Esposito et al., 1977b; Arita & Tagaya, 1980), core polypeptides (Turner & Baxby, 1979) and late intracellular polypeptides (Harper et al., 1979) from several species and isolates of orthopoxviruses have been analysed in one-dimensional polyacrylamide gels. Several differences between species were noted, as were similarities between viruses of uncertain affinities ("Lenny", MK-10-73, buffalopox; see later) and vaccinia virus. However, bands in such gels are identified only by their size and may include monomers and multimers. This disadvantage is lessened when additional information is provided by two-dimensional gels or immunoprecipitation (Ikuta et al., 1979). DNA analysis is at present a simpler and more reliable basis for the identification of orthopoxviruses, but immunoprecipitation may be important in the process of developing species-specific monoclonal antibodies.

## SUMMARY: DISTINCTIONS BETWEEN ORTHOPOXVIRUSES

Poxviruses have larger and more complex virions than most other animal viruses. As a consequence, neutralization tests, which with most viral families are the best method of distinguishing between viral species, are useful only at the generic level, and cross-

neutralization (or cross-protection) provides the most reliable method of allocating an unknown poxvirus to the genus *Orthopoxvirus*.

However, although there is extensive cross-neutralization between all members of the genus, several distinct species exist which differ from one another in a number of biological characteristics, in the size and structure of the genome and in polypeptide composition. Several species are represented by very few independent isolates (ectromelia, camelpox, taterapox, raccoonpox and Uasin Gishu disease viruses), but the properties of the few (or single) isolates of each of these justifies its differentiation as a distinct species. The other 4 species are each represented by many strains, recovered at different times and places.

Variola virus has only been recovered from human subjects and although strains occur which have very different levels of virulence for man, all share many other biological properties and all have very similar genomes.

The other 3 species have wide host ranges. Vaccinia virus has been recovered from a variety of domestic animals and some strains can maintain themselves in nature in rabbits, cows and buffaloes, at least for limited periods of time. However, it seems likely that such infections have originated from human sources. All strains of vaccinia virus share many biological properties and have very similar genomes. Cowpox virus has been recovered from a variety of naturally infected animals, in Europe and the western USSR, but is probably a natural disease of rodents (see Chapter 29). All strains share as characteristic biological properties the production of bright-red haemorrhagic pocks on the CA membrane and the production of A-type as well as B-type cytoplasmic inclusion bodies. Most have larger genomes than those of other orthopoxviruses. Monkeypox virus appears to occur in nature only in western and central Africa, and has been recognized only when infections have occurred in laboratory primates and in man, and once in a wild squirrel. The biological properties of different isolates are very similar, but strains originating from western Africa have rather different genome maps from those recovered in Zaire (see Chapter 29, Fig. 29.1).

## VARIOLA VIRUS

The biological properties of variola virus are enumerated in Table 2.3 and its DNA is

compared with that of other species of *Orthopoxvirus* in Fig. 2.6. It is a specifically human virus, with a narrow host range in laboratory animals, and can be readily distinguished from other orthopoxviruses that can infect man by the distinctive small white pocks produced on the CA membrane (see Plate 2.5).

### Isolation from Natural Sources

Apart from a few bizarre occurrences, such as the infection of a performing monkey described by Mack & Noble (1970), variola virus has been found in nature only as a specifically human pathogen, and thousands of isolations have been made from infected humans. Reported recoveries of variola virus from animal sources (the so-called "whitepox" viruses), described in Chapter 30, are not regarded as providing an exception to this statement.

### Variola Major and Variola Minor

Observations on outbreaks of smallpox in the USA and South Africa at the end of the 19th century and in the USA and the United Kingdom during the early 20th century led to the recognition that, regardless of the vaccination status of the community involved, some epidemics were associated with a high mortality and others with a low mortality (see Chapter 1). Painstaking epidemiological studies by Chapin & Smith (1932) showed that the novel mild variety of smallpox recognized in the USA early in the 20th century "bred true" and never reverted to the severe variety, either in the USA or when it was transported to other parts of the world. This variety of smallpox was called variola minor and the classical form variola major.

Subsequent studies in different geographical areas showed that strains of variola virus which occurred in various parts of the world differed in their virulence for man, producing

case-fatality rates in unvaccinated individuals that ranged from less than 1% to about 40% (see Chapter 4). However, for practical purposes only two clinico-epidemiological varieties of smallpox were recognized: variola major (case-fatality rates, 5–40%) and variola minor (case-fatality rates, 0.1–2%). Recent laboratory studies of strains of variola minor virus recovered from Africa and the USA (or from countries with variola minor originally derived from the USA) revealed that these two groups of variola minor viruses differ in several characteristics (Dumbell & Huq, 1986); it is convenient to distinguish them by calling the USA-derived strains *alastrim virus* and the other strains *African variola minor virus*.

### Laboratory Investigations with Variola Virus

Because of its danger, variola virus was studied much less than vaccinia virus in the laboratory, especially in recent years, after smallpox had been eliminated from most of the countries in which sophisticated laboratory investigations could be carried out. Laboratory investigations were focused on three aspects: (1) the devising of a diagnostic procedure for the recognition of variola virus; (2) finding correlates in laboratory animals of virulence for man; and (3) during recent years, a comparison of the DNAs of strains of variola virus obtained from different parts of the world and the comparison of the DNAs of variola virus and other orthopoxviruses.

### Pathogenicity for Laboratory Animals

Variola virus was one of the first viruses to be inoculated in laboratory animals, when tests were carried out in monkeys and in cows (in attempts to develop strains of "vaccine"). Subsequent investigations showed that it had a much narrower host range than the other orthopoxviruses that infect man (cowpox, monkeypox and vaccinia viruses), and usually produced smaller or less severe lesions than these viruses in the laboratory animals that were susceptible.

All strains of variola virus produce small white pocks on the CA membrane of developing chick embryos (Plate 2.5); this is the most

ST MARY'S HOSPITAL MEDICAL SCHOOL, LONDON, 1978

**Plate 2.12.** Keith Rodney Dumbell (b. 1922). A leading British virologist who has been involved in studies of variola virus and other orthopoxviruses since 1946. He was head of the WHO Collaborating Centre for Poxvirus Research at St Mary's Hospital Medical School, London, England, from 1969 to 1981, and was a member of the Global Commission and several WHO expert groups on poxvirus infections.

useful laboratory test for differentiating variola virus from other poxviruses in material derived from human subjects. The pocks reach a diameter of 0.3–0.6 mm after 3 days' incubation. They are uniform in size, raised above the surface and have clearly demarcated margins. Unlike camelpox virus, the pocks of which develop a small haemorrhagic centre when the eggs are incubated at 35 °C, the pocks produced by variola virus retain their characteristic opaque white appearance at all temperatures. Experienced laboratory workers can accurately differentiate variola virus from all other poxviruses by this test alone.

Another simple and useful test for differentiating variola virus from monkeypox, vaccinia and cowpox viruses is intradermal inoculation in rabbits, since of these four agents only variola virus fails to produce a large and obvious lesion (Plate 2.6). Dumbell & Bedson (1966) showed that variola virus could be adapted to grow serially in rabbit skin if first passed several times in rabbit kidney cell cultures. It then produced a small nodular lesion at the site of intradermal inoculation, but newly isolated and unadapted strains did not produce transmissible lesions in rabbits, although large doses pro-

duced erythema and a small transient papule at the inoculation site.

Some non-human primates are highly susceptible to infection with variola virus and suffer from a disease with a generalized rash, which may be severe and sometimes lethal in chimpanzees and orang-utans. The symptomatology and pathogenesis of primate smallpox are discussed in Chapter 3.

#### *Tests in cows*

During the 19th century the cow was often inoculated with variola virus, in efforts to obtain new strains of "variola vaccinae" for human vaccination. The old literature contains many claims of success for this procedure, largely from German authors—and claims to the contrary, largely from French authors. Some older accounts, although lacking the precision possible with modern virological methods, provide interesting clues about the claimed "transformation" of variola virus into vaccinia virus by passage in cows. Fleming (1880), in a wide-ranging review, considered that after intradermal inoculation variola virus sometimes produced a small lesion in the skin of the cow, from which passage of material to humans caused inoculation smallpox. He supported French authorities such as Chaveau in saying that variola virus could not be carried in series in cows, although in individual cases early passage inoculations might render them resistant to challenge with cowpox or vaccinia virus.

The most recent experiments in cows are those reported by Herrlich et al. (1963), who inoculated 10 calves with very large doses of variola major virus. Only one reacted with small papules, from which variola virus was recovered but the virus could not be further passaged in cows. Only the animal that reacted was found to be immune when subsequently challenged with vaccinia virus.

#### **Growth in Cultured Cells**

In contrast to its limited host range in laboratory animals, variola virus will grow and produce a cytopathic effect in cultured cells derived from many species (Hahon, 1958; Pirsch et al., 1963). However, it grows best in cells from humans and other primates in which it produces characteristic "hyperplastic" foci. In fact, this appearance (Plate

**Plate 2.13.** Hyperplastic foci produced in HeLa cell monolayers by variola virus (A) and lytic plaques produced by vaccinia virus (B). (Similar large plaques are also produced by monkeypox and cowpox viruses.) Monolayers are in the bottom of Microtiter plates, the wells being 6 mm in diameter. Incubation for 48 hours before staining. (From Kitamura & Tanaka, 1973.)

2.13) is not due to proliferation of the infected cells, but to their aggregation. Because of the low cytopathogenicity of variola virus, infected cells remain in the monolayer and are pushed together by the growing non-infected cells around them (Ono & Kato, 1968). Kitamura (1968) described an assay of variola virus based on counting the hyperplastic foci that develop in HeLa and FL cells (Plate 2.13); in primate cells (Vero and JINET) these foci progress to form small plaques (Tsuchiya & Tagaya, 1970).

Variola virus will replicate and produce a cytopathic effect in continuous-line pig embryo kidney cells (Marennikova et al., 1971), a test which has been used to differentiate it from monkeypox virus. However, Veda & Dumbell (unpublished observations, 1974) found that different strains of monkeypox virus varied in their capacity to grow and produce a cytopathic effect in pig embryo kidney cells; some hardly grew at all, others grew moderately well, but none grew as well as variola or vaccinia viruses.

#### *Haemadsorption*

Some of the haemagglutinin that is produced during orthopoxvirus infections appears in the cytoplasmic membrane of the

**Table 2.4.** Haemadsorption in human embryo fibroblasts incubated at 40 °C for 48 hours after being infected with variola virus at a multiplicity of infection of 1 plaque-forming unit per cell<sup>a</sup>

Variety of smallpox	Sources of isolates	Type of haemadsorption		
		Confluent	Focal	Absent
Asian variola major	United Kingdom	15	4	0
	Pakistan	18	8	0
African variola major	Kenya	25	18	0
	United Republic of Tanzania	2	20	0
	Western Africa	2	39	0
Alastrim	Europe and Brazil	0	5	27
African variola minor	Botswana and Ethiopia	6	15	1

<sup>a</sup> From Dumbell & Huq (1986).

infected cells. When susceptible erythrocytes are added to an infected culture they attach to infected cells, a phenomenon known as haemadsorption. Dumbell & Huq (1986) investigated haemadsorption in human embryo fibroblast cultures which were incubated at 40 °C for 48 hours after inoculation with different strains of variola virus. Haemadsorption was classified as confluent, focal or absent (Table 2.4).

Isolates giving confluent haemadsorption were in the majority among the Asian variola major strains and accounted for over half of the Kenyan isolates. Focal haemadsorption was characteristic of most of the other African isolates, but only a few isolates of either Asian variola major or alastrim viruses reacted in this way. Failure to elicit haemadsorption under the conditions of this test was characteristic of the alastrim virus isolates, and, apart from these, was found only in a single isolate from Ethiopia, which was also like alastrim virus in its failure to produce pocks at 38.3 °C (see Fig. 2.8).

Dumbell & Wells (1982) showed that at 38 °C alastrim virus was inhibited in activities that included the insertion of haemagglutinin into the cell membrane (and hence haemadsorption) and release of virus from the cells, although intracellular maturation proceeded normally; strains of variola major virus and most African strains of variola minor virus showed no such inhibition at 38 °C.

#### *Thymidine kinase activity*

Thymidine kinase is an enzyme which occurs in all cells, since it is essential for DNA metabolism. However, all orthopoxviruses produce a virus-coded thymidine kinase in infected cells (Moss, 1978; Bedson, 1982).

Esposito & Knight (1984) have sequenced the thymidine kinase genes of vaccinia, var-

K. McCARTHY, 1971

iola and monkeypox viruses; each differs from the other by some dozen nucleotides (out of 534) and some 5 amino acids (out of 178). Bedson (1982) showed that thymidine kinase produced by each of 11 strains of variola virus (irrespective of geographical origin) was more sensitive to feedback inhibition by thymidine triphosphate than that of any other species of *Orthopoxvirus* (see Table 2.3).

#### **Laboratory Tests for Virulence**

It would clearly have been useful to devise laboratory tests which might have indicated the virulence for man of different strains of

variola virus. Most studies addressed themselves to the problem of differentiating strains that caused variola minor from those that caused variola major. Several tests, outlined below, satisfactorily differentiated strains of alastrim virus derived from the Americas from strains that caused variola major. However, none of these tests distinguished strains of variola minor virus originating in Africa from variola major virus (Dumbell & Huq, 1986).

#### *Pathogenicity for chick embryos*

The first demonstration of a difference between strains of variola major and alastrim viruses in laboratory animals was the finding by Dinger (1956) that variola major virus grew better than alastrim virus in chick embryos. Helbert (1957) then showed that the amounts of variola major and alastrim viruses recovered from the CA membrane in embryos incubated at 35–36 °C were almost the same, but that there was a much higher concentration of virus in the livers of embryos inoculated with variola major virus, and a higher mortality. Dumbell et al. (1961) showed that the mortality was temperature-dependent; both varieties killed embryos at 35 °C but only variola major did so at 37 °C.

Dumbell & Huq (1986) further elaborated Helbert's test of pathogenicity for chick embryos and showed that different strains of variola virus showed a wide spectrum of

response which was not strictly correlated with either virulence or geographical origin. Most strains of Asian variola major virus were of high or moderate pathogenicity. The 8 strains of alastrim virus that were tested were of low or moderate pathogenicity, but strains of variola minor virus from Botswana and Ethiopia showed much the same spectrum of pathogenicity (moderately high to low) as did strains of variola major virus from Kenya. Sarkar & Mitra (1967) reported that different strains of Asian variola major virus differed in their pathogenicity for the chick embryo in eggs incubated at 36 °C.

#### *Ceiling temperature*

Nizamuddin & Dumbell (1961) developed a simple test which reflected the greater temperature sensitivity of growth of alastrim virus compared with variola major virus. A comparison of the numbers of pocks produced on the CA membrane at 35 °C and 38.3 °C allowed an unequivocal distinction to be made between the viruses of variola major and alastrim: variola major virus produced pocks at 38.3 °C but alastrim virus did not. The difference in the temperature sensitivity of viral growth (ceiling temperature) of these two varieties of variola virus could be determined equally well in some lines of cultured cells (Kitamura & Tanaka, 1973).

Subsequent studies confirmed the value of the ceiling temperature as a criterion for

Fig. 2.8. Differences in log titre when incubating each of 196 variola virus isolates from different geographical regions on the chorioallantoic membrane at 35 °C and 38.3 °C. The larger the difference in titre, the greater the sensitivity to a raised temperature (i.e., the lower the ceiling temperature). Each dot is the result of assays of a single isolate; the vertical line shows the median observation for each group of isolates. Alastrim virus = strains of variola minor virus from South America and Europe, originally derived from the Americas. (From Dumbell & Huq, 1986.)

distinguishing alastrim virus (Downie et al., 1963), but strains of variola minor virus of equal or lower virulence from Africa (Botswana, Ethiopia) could not be differentiated from variola major virus by this test (Dumbell & Huq, 1986; Fig. 2.8). One isolate of variola minor virus from Ethiopia stood apart from all others tested in that it resembled alastrim virus in having a low ceiling temperature and failing to produce haemadsorption (Table 2.4). In an earlier study of 61 isolates of variola virus from different geographical locations, including 6 strains from Ethiopia, Shelukhina et al. (1979a) found one Ethiopian strain which resembled alastrim virus in its ceiling temperature and its virulence for mice and chick embryos. The other 5 strains from Ethiopia could not be distinguished from variola major virus by laboratory tests, although they were collected at a time when only variola minor was occurring in Ethiopia.

Initial studies (Bedson et al., 1963; Dumbell & Huq, 1975) suggested that some East African strains that showed lower virulence than Asian variola major were intermediate between variola major and alastrim viruses in their ceiling temperatures. However, attempts to define an "intermediate" strain of variola virus were not successful (Fig. 2.8). Kitamura et al. (1977b), using the temperature sensitivity of the capacity to produce foci in HeLa cells, found that 4 out of 55 strains of variola major virus recovered in India in 1975 were of the "intermediate" level of temperature sensitivity described for some East African strains.

#### Differences in the Virulence of Strains of Variola Major Virus

Another problem, which was studied especially by Sarkar & Mitra (1967, 1968), was whether very severe cases of variola major (haemorrhagic-type and flat-type smallpox, which were almost invariably fatal—see Chapter 1) were caused by more virulent strains of variola major virus than those that caused discrete ordinary-type smallpox. They claimed that strains of variola virus recovered from cases of haemorrhagic-type smallpox were highly virulent for both chick embryos and suckling mice much more frequently than strains derived from discrete ordinary-type smallpox, and suggested that the virulence of the virus was one component in determining the severity of cases of variola major. How-

ever, epidemiological evidence indicates that it was not the most important factor in determining whether a person would suffer from the rare haemorrhagic-type smallpox; physiological factors in the host were probably more important.

On general biological grounds, and by analogy with myxomatosis, a disease in which the assessment of virulence for the natural host was possible by direct testing (see box), it would be expected that a number of strains of variola virus which differed slightly or perhaps substantially in their virulence for man might be circulating at any time in countries in which smallpox was endemic. Because of complexities such as the degree of accuracy of information on cases and/or deaths, the interval since vaccination (if applicable) and age-related differences in case-fatality rates, it was rarely possible to utilize data from smallpox outbreaks other than to determine whether the cause was very mild smallpox (variola minor) or variola major. The significance of apparent differences in case-fatality rates in different outbreaks of variola major were virtually impossible to assess, although most outbreaks in Africa in the 1960s and 1970s had lower case-fatality rates (see Chapters 17–20) than those of variola major in mainland Asia. Unfortunately, except for ceiling temperature tests with alastrim virus, there was no laboratory test of which the results were invariably correlated with virulence for man.

#### Comparison of the DNAs of Strains of Variola Virus

Restriction endonuclease digests of 6 strains of variola virus, derived from outbreaks of variola major and variola minor in Africa, Asia, and Europe, were analysed at the Centers for Disease Control, Atlanta, USA (Esposito et al., 1978; Esposito & Knight, 1985). Physical map locations of the sites of cleavage by the enzyme *Hind*III are compared in Fig. 2.9. Minor differences existed between most strains, but there were no special relationships that correlated with either the virulence of these strains for man or their geographical distribution. All the variola DNAs were clearly very different from those of vaccinia and monkeypox viruses. By comparing gels of DNA fragments from several isolates of variola virus, K. R. Dumbell (personal communication, 1984) showed that DNAs from 4 alastrim strains were

### Variation in the Virulence of Poxviruses

It is notoriously difficult to develop laboratory tests to determine the virulence of viruses. The best that can be done is to test the lethality of virus strains in laboratory animals of the same species as those in which the disease is spreading naturally. For variola virus, virulence tests in man were clearly impossible, and they were not practicable in primates. Sarkar tested many strains of variola major virus from Calcutta in chick embryos and baby mice and produced some evidence of differences in virulence for these hosts that appeared to be correlated with virulence for man, but other virologists were unable to reproduce these results, although few attempted to do so. Further, the fact that the highly lethal haemorrhagic-type smallpox usually produced discrete ordinary-type smallpox in case contacts led most epidemiologists to question the relevance of these results. Certain laboratory tests were successfully used for distinguishing one strain of variola virus of low virulence (alastrim virus) from variola major virus, but failed to distinguish between the equally mild African variola minor virus and variola major virus (Dumbell & Huq, 1986).

The variations in virulence that might be expected in a poxvirus that has been spreading naturally for some years can be assessed in animal models. Myxomatosis in the rabbit, *Oryctolagus cuniculus*, provides a good example, in which the lethality and survival times in groups of rabbits were used as the test for virulence of the virus (Fenner & Ratcliffe, 1965; Fenner, 1983). Two different strains of myxoma virus (a member of the genus *Leporipoxvirus*) were used to initiate the disease among wild rabbits in Australia and Europe, and it became enzootic in both continents. Initially both introductions caused very high mortalities (over 99% case-fatality rates), but within a few years tests of the virus in genetically unselected laboratory rabbits showed that a wide range of strains of different virulence had evolved, although no strain has yet been recovered from naturally infected rabbits that is as attenuated as some strains derived by laboratory manipulation. This example shows that with a virus that was initially extremely virulent, several different strains which differed substantially in virulence arose within a few years and persisted in nature. This development occurred within a decade; it seems highly likely that a similar range of strains of variola virus of different virulence for man occurred in countries in which smallpox had been endemic for centuries.

Fig. 2.9. Dendrogram illustrating the similarities and differences between *Hind*III cleavage sites on 6 variola DNAs, compared with 4 monkeypox and 2 vaccinia DNAs (see legend of Fig. 2.7). Number of attributes = 36. Origin of DNAs as indicated; V. maj. = variola major; V. min. = variola minor; Mpox = monkeypox. Full details of the origins of the viral strains are given in Esposito & Knight (1985), from which the data on restriction sites were derived.

similar but differed from the DNA of the classical variola major strain, Harvey, whereas the DNAs of all the variola minor isolates from Africa (Botswana, Ethiopia and Somalia) resembled that of Harvey, rather than those of alastrim virus.

Digestion with *SaI*I showed that the two Netherlands "whitepox" virus isolates (see Chapter 30) were identical with a strain of variola virus from Vellore, India, that had been handled in the laboratory at the time of their recovery—a pattern that was unique among 21 strains of variola virus examined (Dumbell & Kapsenberg, 1982).

Most of the data on DNA mapping illustrated in this chapter involve the use of the restriction endonuclease *Hind*III. Comparison of single strains of variola, vaccinia and monkeypox viruses using 5 other restriction endonucleases (*Ba*I, *Sma*I, *Kpn*I, *Sa*I and *Xho*I) confirmed the conclusions about their relationships derived from analyses with *Hind*III (Esposito & Knight, 1985).

### Differences between the DNAs of Variola and Monkeypox Viruses

Because variola virus and monkeypox virus both cause a severe generalized poxvirus infection of man, special attention has been devoted to comparing their DNAs. Dumbell and his colleagues have used two techniques: fine structure mapping of equivalent *Hind*III fragments and analysis of heteroduplex formation, as revealed by electron microscopy.

Using the first method, Dumbell & Dollery (personal communication, 1984) have examined 7 corresponding cloned *Hind*III fragments of variola and monkeypox viruses, all derived from the central conserved position of the genome, with 20 restriction endonucleases. Their results are summarized in Table 2.5. There were between 2 and 6

(average 3.4) cleavage sites per kilobase pair (kbp), and the percentage of sites not shared varied, for different fragments, between 20% and 50% (average 30%).

Using similar cloned fragments of these two viruses, Kinchington et al. (1984) compared the threshold denaturation by formamide of homoduplexes and heteroduplexes. This method is sensitive and revealed a region of significant heterogeneity occurring in 4–6 kbp out of 43–45 kbp of the conserved region. The method has considerable potential and important conclusions can be expected to emerge from its further exploitation.

### Genetic Studies

Because in recent years variola virus could be handled only in microbiologically highly secure laboratories, very few genetic studies have been carried out with it. However, as would be expected from the generality of recombination throughout the *Orthopoxvirus* genus (Woodroffe & Fenner, 1960), mixed infection of cells with variola virus and another orthopoxvirus was found to yield some hybrid progeny. Such progeny were obtained from mixed infections with rabbitpox and alastrim viruses (Bedson & Dumbell, 1964a) and cowpox and variola major viruses (Dumbell & Bedson, 1964; Bedson & Dumbell, 1964b). It was hoped that study of the latter might provide information on the origin of vaccinia virus.

By using the phenomenon of non-genetic reactivation (see above) and incubating inoculated eggs above the ceiling temperature of the active virus (variola minor or variola major viruses) many hybrid clones were obtained. These clones appeared to be stable in their biological characteristics; they showed a wide variety of combinations of properties, some being like those of one or other of the

parental species, others being intermediate (Table 2.6).

Each of the 7 markers examined by Bedson & Dumbell (1964b), as well as sensitivity of the viral thymidine kinase to inhibition by thymidine triphosphate, studied later by Bedson (1982), and the presence of the "d" antigen (Rondle & Dumbell, 1982), was capable of segregating independently. The authors suggested that if enough hybrids were tested it would be possible to obtain one that resembled vaccinia virus in all these biological properties. However, it is unlikely that the restriction map of the DNA of such a virus would resemble that of vaccinia virus.

### Species Diagnosis

The most useful biological characteristics for species diagnosis of variola virus are the production of small dense white pocks (0.3–0.6 mm in diameter) on the CA membrane, with a low ceiling temperature (37.5 °C for alastrim virus and 38.5 °C for all other strains), the low virulence for mice and chick embryos, the failure to grow in rabbit skin and the capacity to produce a cytopathic effect in pig embryo kidney cells and hyperplastic foci in HeLa cells. When these characteristics were found in material obtained from a case of suspected smallpox they constituted positive confirmation of the diagnosis; indeed, the recovery of typical variola virus pocks on the CA membrane was usually accepted as diagnostic.

It is worth noting, however, that combinations of properties rather like this are found with both camelpox virus and taterapox virus (Table 2.3). The source of the material usually removes any uncertainty; neither camelpox virus nor taterapox virus has ever been found to produce disease in man and variola virus has never been recovered from animals under conditions in which no suspicions arose of laboratory contamination (see Chapter 30). The 3 viruses can also be differentiated by laboratory tests:

(1) Only variola virus produces dense white pocks at all temperatures of incubation at which pocks develop.

(2) Variola virus produces hyperplastic foci and camelpox virus produces giant cells in several human and primate cell lines (Baxby, 1974).

(3) Taterapox virus is serially transmissible in rabbit skin (Gispen, 1972); variola virus is not.

(4) Taterapox virus is cytotoxic for RK 13 cells, in which variola virus produces hyperplastic foci (Huq, 1972).

(5) Only variola virus produces a generalized disease in primates.

A definitive diagnosis of variola virus can be made by restriction endonuclease digestion of the viral DNA (see Fig. 2.6 and 2.9).

### VACCINIA VIRUS

The vast bulk of experimental work on *Orthopoxvirus* as a genus and *Poxviridae* as a

family has been carried out on one species—vaccinia virus (see Holowczak, 1982; Fenner et al., 1987). It has also been used as a live virus vaccine more extensively, and for a much longer period, than any other immunizing agent.

### Isolation from Natural Sources

The problem of the origin or origins of vaccinia virus is considered in Chapter 7. Here it is relevant to mention that the virus has been isolated from skin lesions of several species of domestic animals (Table 2.7). During periods when vaccination of humans against smallpox was being vigorously pursued there were clearly numerous opportunities for infection to be transferred from recently vaccinated persons to various domestic animals, with subsequent spread in herds either by milkers acting as vectors or by some other route.

Some cases of "cowpox" in cattle (Dekking, 1964; Dahaby et al., 1966; Maltseva et al., 1966; Topciu et al., 1976) and of "camelpox" in camels (Krupenko, 1972) have been caused by vaccinia virus. It is likely that all cases of buffalopox (Lal & Singh, 1977), in both Egypt and India, were caused by vaccinia virus. Although one strain of "buffalopox" virus had a ceiling temperature of 38.5 °C (Baxby & Hill, 1971), it had the DNA map of vaccinia virus (K.R. Dumbell, personal communication, 1983). As recently as 1986, buffalopox has been reported from several areas in central India. Four isolates recovered from infected buffaloes were shown by *Hind*III electropherograms to be strains of vaccinia virus (K. R. Dumbell, personal communication, 1986).

Rabbitpox virus warrants particular mention, since it has been extensively used in

studies of pathogenesis and orthopoxvirus genetics, including the construction of the first DNA map of vaccinia virus. The name was first given to a strain of vaccinia virus that caused severe epidemics in laboratory rabbit colonies in New York in 1933–1934 (Greene, 1933; Rosahn & Hu, 1935). Subsequently, a similar virus of high virulence for rabbits was recovered from a colony of rabbits in Utrecht, Netherlands, under conditions which were said to preclude the infection of the animals with vaccinia virus (Jansen, 1946). Both would be classified as "neuro-vaccinia", in that they are highly virulent by intracerebral injection in rabbits and produce ulcerated haemorrhagic pocks on the CA membrane.

Two viruses recovered in unusual circumstances in central and western Africa, termed "MK-10-73" and "Lenny" respectively, were proved by DNA mapping to be strains of vaccinia virus with a lower ceiling temperature (39.5 °C and 38.5 °C respectively) than standard strains (41 °C) (K.R. Dumbell, personal communication, 1984). MK-10-73, said to have been isolated from the kidney of a wild monkey captured in Zaire, was processed in Moscow (Shelukhina et al., 1975). "Lenny" was recovered from a severely malnourished Nigerian woman who died after an illness with fever and a generalized rash that was very like eczema vaccinatum (Bourke & Dumbell, 1972). The origin of these strains is obscure. Temperature-sensitive (*ts*) mutants of vaccinia virus are readily obtainable in the laboratory (Chernos et al., 1978; Dales et al., 1978; Sambrook et al., 1966). Contamination at some stage cannot be excluded with MK-10-73. "Lenny" resembles the Wyeth strain of vaccinia virus, then being used for vaccination in Nigeria, in all biological properties except the ceiling temperature (K.R. Dumbell, personal communication, 1984); presumably it was a naturally occurring *ts* mutant, perhaps selected by the unusual conditions under which it grew (it was obtained 16 days after the rash appeared).

Table 2.7. Animals from which vaccinia virus has been recovered (infection from human sources always possible)

<sup>a</sup> Possibly a contaminant, from the field (Zaire) or in the laboratory.

### The Variability of Strains and their Pathogenicity

In sharp contrast to variola virus, which has a narrow host range, vaccinia virus has a very wide host range and grows rapidly and to high titre in many species of animals and in most kinds of cultured cells. In chick embryos,

it produces large pocks on the CA membrane within 48 hours, whereas other orthopoxviruses produce smaller pocks and take 3 days to reach the optimum size for pock counts.

#### *Neurovaccinia and dermal vaccinia*

Two terms occur in older works on vaccinia virus that need some explanation: "dermal vaccinia" and "neurovaccinia". Early workers usually maintained vaccinia virus by passage through calves, sheep or rabbits, the animals usually being inoculated by scarification (see van Rooyen & Rhodes, 1948). When the skin lesions reached a sufficient size the infected skin area was scraped, the material thus obtained being called "dermal vaccinia" or "dermovaccine". Strains of vaccinia virus that were maintained by intracerebral inoculation of rabbits, sometimes with occasional testicular passage (Levaditi et al., 1922, 1938), were called "neurovaccinia".

#### *Differences between strains of vaccinia virus*

Two systematic studies have been made of the biological characteristics of various laboratory strains of vaccinia virus (Fenner, 1958; Ghendon & Chernos, 1964). A variety of differences were found, involving the production of haemagglutinin, heat resistance of the virion, pathogenicity in rabbits and mice (Fenner, 1958; Table 2.8), and plaque morphology and virulence for monkeys (Ghendon & Chernos, 1964). The traditional division of strains into "dermovaccine" and "neurovaccine" broadly differentiated viruses of lower and higher virulence for the laboratory animals used; in particular, the occurrence of haemorrhagic pocks on the CA membrane was correlated with the produc-

tion of large indurated skin lesions with a purple centre following the intradermal inoculation of rabbits. White pock mutants of the "neurovaccine" strains produced small pink nodules in the rabbit skin.

Some strains or mutants of vaccinia virus fail to produce haemagglutinin. Rabbitpox virus (Utrecht strain) is one example (Fenner, 1958). Another HA<sup>-</sup> mutant (IHD-W) produces a non-glycosylated form of the 89 000 molecular weight polypeptide, the glycosylated form of which Payne (1979) identified as the haemagglutinin. As with rabbitpox virus, infection with the mutant did not evoke the production of haemagglutinin-inhibiting antibodies, suggesting that glycosylation must produce an important conformational change in the secondary structure of the polypeptide.

#### *Differences in DNAs of different strains of vaccinia virus*

In spite of this variability in biological characteristics, all strains of vaccinia virus that have been examined have remarkably similar DNAs, as judged by restriction endonuclease analysis. Fig. 2.10 illustrates the similarity between the DNAs of 5 strains of vaccinia virus and their difference from variola and monkeypox DNAs, using three restriction endonucleases. The vaccinia strains compared included a classical "neurovaccinia" strain (rabbitpox Utrecht) and two classical dermal strains (LS and HI).

#### **Variation within a Strain**

Several investigators have shown that uncloned stocks of most orthopoxviruses are in

Table 2.8. Some biological characteristics of several different laboratory strains of vaccinia virus<sup>a</sup>

<sup>b</sup> R = red; W = white; U = ulcerated; O = non-ulcerated.

<sup>c</sup> +++ = large papule with haemorrhage and necrosis; + = small papule; 0 = insignificant lesion.

fact mixtures of genetically dissimilar virions. For example, since orthopoxviruses which produce haemorrhagic pox yield, on cloning, a substantial proportion of white non-ulcerated pox (varying between 0.01% and 1%, according to species; Gemmell & Fenner, 1960; Dumbell & Archard, 1980), stock preparations of those viruses must contain several different white pox mutants.

Using other methods of assay, stocks of vaccinia virus which appear to be homogeneous with respect to the type of pox produced can sometimes be shown to be mixed, either in the plaques produced on selected kinds of cells (Ghendon & Chernos, 1964) or by heterogeneity in the patterns produced on analysis with restriction enzymes (Wittek et al., 1978).

### Genetic Studies

Genetic recombination occurs when single cells are co-infected with two strains of virus with several different marker properties. Early experiments on recombination (Fenner, 1959) utilized a "dermal" and a neurovaccinia strain (rabbitpox). Subsequently, the observation that all vaccinia strains producing ulcerated haemorrhagic pox on the CA membrane yielded white pox mutants (Fenner, 1958) led to the demonstration of recombination between some of these mutants but not others (Gemmell & Fenner, 1960). Certain white pox mutants were shown to be host-cell-restricted conditional lethal mutants (Fenner & Sambrook, 1966). Unlike the wild-type virus and some of the white pox

mutants, they failed to replicate in pig kidney cells. Subsequent studies (Lake & Cooper, 1980) showed that the pig-kidney-cell-restricted mutants had deletions at the left-hand terminus and the white pox mutants that grew in pig kidney cells had deletions at the right-hand terminus of the rabbitpox virus genome. Although segments of DNA were lost in the terminal deletions, the changes were not always simple deletions; terminal sequence duplication and transposition were also involved (Moyer et al., 1980).

Suites of temperature-sensitive conditional lethal mutants of rabbitpox and vaccinia viruses have also been assembled (Sambrook et al., 1966; Padgett & Tomkins, 1968; Chernos et al., 1978) and have been employed in experiments on the biogenesis of vaccinia virus (Dales et al., 1978).

A new era in poxvirus genetics began when fragments of vaccinia virus DNA obtained after digestion with restriction endonucleases were cloned in *Escherichia coli* (Wittek et al., 1980). The whole genomes of several strains of cowpox, vaccinia and variola viruses have now been cloned, and detailed analysis of the structure and function of poxvirus DNA has begun. In other experiments based on cloned viral DNA, fragments of foreign DNA have been incorporated into the vaccinia virus genome and expressed during infection (Smith et al., 1983). This opens up the possibility that after suitable genetic manipulation vaccinia virus may be used for the vaccination of humans or domestic animals against diseases caused by a variety of infectious agents other than orthopoxviruses (Quinnan, 1985).

Fig. 2.10. Dendrogram illustrating the similarities and differences between *Hind*III, *Sma*I, and *Xho*I cleavage sites on DNAs from 5 vaccinia strains originating in different countries, compared with 2 monkeypox and 2 variola DNAs (see legend of Fig. 2.7). Number of attributes = 66. Full details of the origins of the viral strains are given in Esposito & Knight (1985), from which the data on restriction sites were derived.

### Species Diagnosis

As illustrated in Fig. 2.7 and in more detail by Mackett & Archard (1979), the genome of vaccinia virus is distinctive, and comparison of DNA maps provides conclusive evidence whether any isolate under examination belongs to this species. Biological characteristics that are particularly useful for diagnostic purposes are the rapid growth of large pocks on the CA membrane, which may vary from haemorrhagic to dense white in appearance, the high ceiling temperature of growth on the CA membrane (41 °C or higher) and the broad host range.

### COWPOX VIRUS

Cowpox virus is of interest in the context of smallpox eradication because of its historic involvement in the discovery of vaccination (see Chapter 6) and because it is transmissible to man (see Chapter 29). Research over the last decade has shown that there is a large number of somewhat similar viruses which can cause infections in a variety of animals, rodents probably being the reservoir hosts (see Chapter 29). In this book all these viruses are included within the cowpox virus species.

#### Cowpox and Horsepox in Europe

The occurrence of a sporadic pox disease of cows transmissible to man had been known for centuries and was brought to public attention by the observations of Jenner. The distinctive character of the usual cause of cowpox—the *Orthopoxvirus* species now categorized as “cowpox virus”—was first recognized by Downie (1939a,b). Other causes of what is called “cowpox” are vaccinia virus, usually derived from a human source, and a species of *Parapoxvirus* that causes milker's nodules in man. The last-named virus was one of the causes of Jenner's “spurious cowpox”. It is only the first of these 3 viruses with which we are concerned here.

“Horsepox” is a tantalizing disease for a modern virologist who is interested in the history of Jenner's vaccine. Jenner confused the situation by suggesting that cowpox in cows usually originated from “grease” of horses—a lesion of the fetlocks (Plate 2.15A) that may be caused by several different agents, most commonly the bacterium *Dermatophilus*

*congolensis* (Gillespie & Timoney, 1981). During the 19th century, a poxvirus (“horsepox virus”) was an occasional cause of this syndrome. Loy (1801) demonstrated that material from such a lesion produced cowpox when inoculated in cows' teats, and he protected a child from challenge variolation by “equination”. Usually, according to Crookshank (1889), horsepox was associated with pustular lesions on the perineum or the head of the horse (Plate 2.15B), as well as sometimes on the fetlocks (grease). Both Chaveau (cited by Crookshank, 1889) and Fleming (1880) believed that horsepox was due to the accidental infection of horses with cowpox virus. Evidence now available suggests that both cowpox and in the past at least some cases of horsepox were due to the incidental infection of these animals by cowpox virus, which probably circulates in rodents; or, as Jenner suggested, it may have been transferred accidentally from horses to cows, or vice versa, by man. More recently horsepox, like “cowpox”, has been produced by the infection of horses with vaccinia virus originating from vaccinated human subjects (Kii & Ando, 1937). Finally, Baxby (1981) has suggested that horsepox, which he postulates was a disease distinct from the infection of horses with cowpox virus, and which became extinct at about the end of the 19th century, was in fact caused by vaccinia virus.

#### Genetic Studies

White pock mutants, which have been important for genetic studies of orthopoxviruses and in speculations about the evolution of both vaccinia and variola viruses, were first recognized in experiments with cowpox virus inoculated on the CA membrane (Downie & Haddock, 1952; Tongeren, 1952). Early attempts to exploit this system for genetic studies of cowpox virus were frustrated by the failure to obtain recombination between many combinations of separately isolated mutants derived from the Brighton strain of cowpox virus (Dumbell, unpublished results, 1960; Greenland & Fenner, unpublished results, 1960). This failure was explained by the discovery that all white pock mutants of the Brighton strain involved substantial deletions from the right-hand end of the genome (Archard & Mackett, 1979).

Amano et al. (1979) found that all white pock mutants of cowpox virus failed to

M. SOEKAWA

**Plate 2.15.** **A:** Grease, a lesion of the fetlocks caused by a variety of agents. **B:** Horsepox. Illustration of a case investigated by Professor Peuch of Toulouse, which occurred during an outbreak of horsepox in Toulouse in 1880. (B from Crookshank, 1889.)

produce an early cell-surface antigen that was produced in infected cells by all the parental strains (10 wild-type and 28 white pock mutants were investigated). Randle & Dumbell (1962) showed that another antigen, "d", which was present in extracts of cells infected with wild-type cowpox virus did not occur in its white pock mutants. Subsequently, Randle & Dumbell (1982) demonstrated that "d" antigen occurred in several orthopoxviruses that produced necrotic haemorrhagic lesions after intradermal inoculation in rabbits (cowpox virus, neurovaccinia strains including rabbitpox virus, and certain recombinants between cowpox and variola viruses), but not in those that did not produce such lesions (cowpox white mutants, variola and some recombinants between variola and cowpox viruses—see Table 2.6).

### Species Diagnosis

The most reliable biological indicators of cowpox virus are the production of large haemorrhagic pocks on the CA membrane, with a ceiling temperature of 39 °C, the production of a large haemorrhagic lesion after intradermal inoculation in rabbits, the

wide host range, and the production of A-type as well as B-type inclusion bodies in infected cells. Although there is greater variability between the DNA maps of different strains of cowpox virus (using the broad definition adopted here) than is the case with other species of *Orthopoxvirus* (see Chapter 29; Fig. 29.4), all strains of cowpox virus cluster together in the dendrogram and can be readily differentiated from other orthopoxviruses.

### LABORATORY CONFIRMATION OF SMALLPOX DIAGNOSIS

Laboratory methods played a crucial role in the global smallpox eradication campaign; indeed the achievement of eradication could not have been confidently certified without their use. The development of laboratory support for the Intensified Smallpox Eradication Programme is outlined in Chapter 10. The laboratory also provided support for the clinical diagnosis of smallpox. This was not of much importance in endemic countries when smallpox was a common disease, but was of great value in non-endemic countries confronted with suspected imported cases (Mac-

rae, 1982) and in the endemic countries as eradication approached (Ježek et al., 1978f).

### Preparation of a Guide for Laboratory Diagnosis

In October 1967 a WHO Scientific Group on Smallpox Eradication met in Geneva. Among other recommendations, it proposed that laboratories for diagnosis should be developed in each of the larger countries and regional laboratories should be designated to serve groups of smaller countries (WHO Scientific Group on Smallpox Eradication, 1968). In April 1968 a group of experts met in Philadelphia, USA, to commence the preparation of a manual, *Guide to the Laboratory Diagnosis of Smallpox for Smallpox Eradication Programmes*, which was intended to provide information on procedures that could be performed in the surveillance activities of smallpox eradication programmes in endemic areas.

The guide, which incorporated the comments of a number of other experts, was published in 1969 (World Health Organization, 1969a). It described methods of specimen collection, microscopic examination of smears (by the method of Gispén, 1952), precipitation in gel, isolation of virus on the CA membrane, the maintenance of records and the layout of a smallpox diagnostic laboratory (see Chapter 30, Fig. 30.3A). In retrospect, the value of the guide can be assessed by a review of the changes that occurred as the eradication programme proceeded.

(1) Examination of stained smears was not widely practised, and in developed countries this method was completely displaced by electron microscopic examination of negatively stained preparations.

(2) The guide facilitated the development of national diagnostic laboratories in some heavily populated countries, such as India and Bangladesh. As eradication approached in these countries, duplicate specimens were sent to the WHO collaborating centres (see Chapters 15 and 16).

(3) The concept of a regional laboratory network did not materialize; instead reliance was placed on the services of the WHO collaborating centres in Moscow, USSR, and Atlanta, USA.

(4) A special kit was later developed for the collection and dispatch of specimens (see Chapter 10, Plate 10.6).

### Methods of Laboratory Diagnosis

Laboratory diagnostic methods used can be divided into three groups: those involving the recognition of virions or of viral antigens in material collected from the patient, and inoculation of the virus in laboratory animals (including the CA membrane) or cultured cells. Subclinical infection with variola virus or the retrospective diagnosis of human monkeypox could be recognized only by serological tests (see Chapters 1, 3 and 29). Detailed descriptions of techniques are given by Downie & Kempe (1969) and Nakano (1979, 1982).

#### *Methods involving the recognition of virions*

*Staining for light microscopy.* In smallpox, virions occurred in vast numbers in the vesicle fluid and in pustules and scabs, and pathologists developed a variety of staining methods which made it possible to see the virions in stained smears. Paschen's method (Paschen, 1906), using basic fuchsin, which stained the virions deep red, was probably the most widely used (see Plate 2.1); it was subsequently replaced by silver impregnation techniques (Morosow, 1926; Gispén, 1952). Gispén's method was advocated in the aforementioned WHO *Guide to the Laboratory Diagnosis of Smallpox for Smallpox Eradication Programmes* (World Health Organization, 1969a) as the method of choice for the presumptive diagnosis of smallpox. In skilled hands it was a useful test but was open to misinterpretation by those not familiar with the technique—especially after the lesions became pustular—and it was not widely used.

*Electron microscopy.* Nagler & Rake (1948) were the first to employ electron microscopy for the diagnosis of smallpox, using shadow-cast preparations of crusts or vesicle fluid that had previously been purified and concentrated by centrifugation. However, widespread use of electron microscopy as a diagnostic method was not feasible until the negative staining technique was introduced by Brenner & Horne in 1959. Peters et al. (1962) and subsequently Cruickshank et al. (1966) showed the value of this method for recognizing poxvirus or herpesvirus particles in vesicle fluid and scabs taken directly from patients. Like the examination of stained smears, electron microscopy could not be used to distinguish between variola, vaccinia and monkeypox viruses, which are morphologi-

**Plate 2.16.** Virions of variola virus (A and B) and varicella virus (C) as seen in negatively stained preparations submitted for diagnosis to the WHO Collaborating Centre at the Centers for Disease Control, Atlanta, GA, USA. Bar = 100 nm.

cally indistinguishable, but it was of great value in confirming or possibly excluding poxvirus infection and in distinguishing between poxvirus infection and chickenpox. In 1971 it became an integral part of the diagnostic procedures used by the WHO collaborating centres in Atlanta, USA, and Moscow, USSR. Plate 2.16 shows typical virions of variola virus along with those of herpesvirus (from a patient with chickenpox), as seen in negatively stained specimens of crusts, scrapings or vesicle fluid.

#### *Methods involving the recognition of viral antigens*

Initially, complement-fixation and flocculation tests were used for the demonstration of orthopoxvirus antigens in vesicle or pustule fluid, the former test being considered preferable (Craigie & Wishart, 1936; Downie, 1946). Subsequently, gel precipitation was developed, and an adaptation of this method on microscope slides was described in detail in the WHO guide. This technique was extensively employed in some national campaigns (e.g., in India; Ježek et al., 1978f) in laboratories that did not have an electron microscope available for rapid diagnosis. With adequate amounts of recently collected antigen it was a quick and accurate test (Rao et al., 1970; A.W. Downie, personal communication, 1981).

Other serological tests for viral antigen were sometimes used but never became widely popular. Kitamura et al. (1977a) suggested that direct immunofluorescence could be used for rapid diagnosis in the field, but they and other workers (Tarantola et al., 1981) recorded a number of false positive results, a major disadvantage as the achievement of eradication approached.

#### *Tests in animals and isolation of the virus*

All the methods described so far had the limitation that, if positive, they did not distinguish between different orthopoxviruses. This drawback was of little significance when smallpox was a common disease, but it became increasingly important as eradication proceeded, particularly after human monkeypox was recognized in 1970.

In the early days of virology the only animal diagnostic procedure useful in distinguishing variola virus from varicella virus was the inoculation of monkeys, clearly a method that could not be widely used. Paul's test, which involved the scarification of the rabbit cornea, provided a more widely applicable method, but according to Downie (1946) and Marennikova et al. (1961), it often gave false negative results. However, variola virus produced very characteristic pocks on the CA membrane, which provided a simple and reliable laboratory method for isolating and recognizing that virus.

*Production of pocks on the CA membrane.* It had been known since the 1930s that orthopoxviruses grew on the CA membrane of developing chick embryos, and that when dilute suspensions were used different strains of vaccinia virus produced characteristic pocks. Although others had cultivated variola virus on the CA membrane, Downie & Dumbell (1947b) were the first to demonstrate the reproducible and clear-cut differences between the pocks produced by variola virus and those due to vaccinia virus. CA membrane inoculation soon became the method of choice for the isolation of variola virus (World Health Organization, 1969a). The pocks produced by variola virus are quite

distinctive and can be readily distinguished from those produced by the other orthopoxviruses that are pathogenic for man—vaccinia, cowpox and monkeypox viruses (see Plate 2.5). It has remained the method of choice for the preliminary identification of orthopoxviruses, and it was the fact that the pock morphology of monkeypox virus was different from that of variola virus that led Marennikova et al. (1972a) to make the first laboratory diagnosis of human monkeypox.

*Isolation in cultured cells.* Most human and non-human primate cells, and some cells derived from other species (rabbit kidney and pig embryo kidney cells), are susceptible to infection with variola virus. In most cell systems variola virus causes cell fusion and multinucleated foci; the small (1–3 mm in diameter) hyperplastic foci are quite distinctive when compared with the large (2–6 mm in diameter) plaques produced by vaccinia, monkeypox and cowpox viruses (Kitamura, 1968; see Plate 2.13). Pig embryo kidney cells are unusual in that variola virus, which has a narrow host range, produces a cytopathic effect, whereas most strains of monkeypox virus, which has a wide host range, do not (Marennikova et al., 1971).

Although cell culture was sometimes more

sensitive (Nakano, 1979), inoculation on the CA membrane was generally a more useful test with field material, since positive results could be obtained even with scabs that were contaminated with bacteria (Sarkar & Mitra, 1963), which usually destroyed cell cultures. Also, if the content of viable virus was low it often took several days, and perhaps serial passage, before characteristic lesions occurred in cultured cells, whereas a result could always be obtained within 3 days by CA membrane inoculation.

*Differentiation between orthopoxviruses.* Four species of *Orthopoxvirus* can produce lesions in man: variola, monkeypox, vaccinia and cowpox (see Chapter 29). Each produces distinctive pocks on the CA membrane; in addition, the 4 species can be differentiated by several other biological properties (Table 2.9) as well as by restriction endonuclease mapping of their DNAs.

### Comparison of Different Laboratory Diagnostic Methods

Noble et al. (1970) assessed the value of various laboratory procedures for the diagnosis of variola minor in Brazil. They always

obtained positive results with both scabs and vesicular or pustular fluid stored in capillary tubes and tested by electron microscopy and cultivation on the CA membrane; a few such specimens were negative by gel precipitation. They were less successful with material that had been stored as smears on glass slides for up to 2 months at room temperature. In searches with the electron microscope for a maximum period of 10 minutes for each specimen, only 30 out of 52 (58%) were positive. Some of these showed structural degeneration of the virus particles; presumably this had proceeded so far on those diagnosed as negative that no intact virions could be found during the 10-minute search. Twenty-seven out of the 30 specimens found positive by electron microscopy yielded virus when inoculated on the CA membrane; 1 specimen found negative by electron microscopy was positive on CA membrane inoculation. Positive culture was never obtained by serial passage of membranes that appeared normal; occasionally

membranes that had cloudy or non-diagnostic opacities on first inoculation showed unequivocal variola virus pocks on the second passage. Only 41% of the stored smears were positive by gel diffusion.

The most comprehensive analysis of the laboratory diagnosis of smallpox was reported by Nakano (1973), who kindly updated the figures in 1982 to show the situation at that time (Table 2.10). The material under study had been shipped to the Centers for Disease Control, Atlanta, USA, from Africa, South America and Asia and had usually been in transit for between 2 and 4 weeks, and occasionally longer, often at high ambient temperatures. Four methods were used: electron microscopy, gel precipitation, and cultivation on the CA membrane and in Vero cells. By March 1981 a total of 6919 specimens had been examined, many of them from suspected chickenpox cases during precertification testing in Ethiopia and Somalia. Of the 981 positive specimens, 940 were identified as

Table 2.10. Relative efficiency of 4 laboratory methods for diagnosing variola or human monkeypox infections. Tests on material from vesicles or scabs in 981 positive specimens from 6919 cases of suspected smallpox or monkeypox, accumulated between January 1966 and March 1981<sup>a,b</sup>

variola virus and 41 as human monkeypox virus.

Electron microscopy had the advantage of being much the most rapid method of making a presumptive diagnosis, which was a very important requirement, especially in non-endemic countries. In scabs or material that had been some time in transit, it was also the most sensitive, although fields might have to be searched for as long as 30 minutes before a specimen was declared negative. The longer period of search undoubtedly accounted for the greater percentage of successes recorded by Nakano with stored specimens, compared with the experience of Noble et al. (1970). Inoculation on the CA membrane had the great advantage of allowing differentiation between the 4 orthopoxviruses that can infect man (variola, monkeypox, cowpox and vaccinia viruses). It was also the most sensitive with fresh specimens of vesicular fluid, since one infectious particle was potentially capable of producing a pock. Positive results were obtained on the CA membrane with 14 specimens that were negative by electron microscopy, whereas 97 specimens were positive by electron microscopy but negative by CA membrane inoculation. However, Nakano (1979) found that the susceptibility of the CA membrane, although usually quite satisfactory, was sometimes unacceptably low, as judged by control inoculation in cultured cells. For this reason he found it useful to make inoculations on cultured cells, especially with critical specimens in which recovery of the responsible virus was very desirable (e.g., in suspected human monkeypox). Out of 186 specimens that were tested by all 4 methods, 182 were positive by electron microscopy, 135 by tissue culture inoculation and 117 by CA membrane inoculation—i.e., 18 specimens were positive by tissue culture but negative on the CA membrane. Growth in pig embryo kidney cells was sometimes used to differentiate between variola and monkeypox viruses. Nakano confirmed the finding of Noble et al. (1970) that gel precipitation was the least sensitive technique and that it was often negative in lesion material that had been exposed to ambient temperatures for several days.

#### Tests for Species-Specific Viral Antibodies

Most serological tests for orthopoxvirus antibodies were positive in the late stages of

smallpox, except in some cases of haemorrhagic-type smallpox, which were in any case fatal, but the detection of antibodies was irrelevant for the ordinary laboratory diagnosis of smallpox. However, serological tests were useful in determining whether certain patients who had recovered from a febrile illness associated with a rash had suffered from smallpox. They provided the only way of diagnosing variola sine eruptione and sub-clinical infections, the complement-fixation test being particularly valuable because of the short period after infection that it remained positive (see Chapter 1).

Serological tests were important in another context—namely, the specific diagnosis of prior infection with monkeypox virus, whether in humans or in animals (see Chapter 29). Several attempts were made to develop methods for differentiating between antibodies due to prior infection with variola, monkeypox and, in certain cases, other orthopoxviruses (see Chapter 3). The methods described depended on the multiple absorption of positive sera and the recognition of antibody to a particular viral species after such absorption. Immunoprecipitation (Gispen & Brand-Saathof, 1974) and immunofluorescence (Gispen et al., 1974) were used to differentiate antibodies due to infection with variola, monkeypox and vaccinia viruses. Subsequently, Hutchinson et al. (1977) and Marennikova et al. (1981) developed absorption tests for detecting specific antibodies using radioimmunoassay and ELISA respectively. All these methods required that adequate amounts of relatively potent serum should be available for testing, and the requisite multiple absorptions were tedious and time-consuming. However, they were useful in providing evidence of past monkeypox virus infection in man and in certain species of monkeys and squirrels.

#### RESISTANCE TO PHYSICAL AND CHEMICAL AGENTS

The infectivity of orthopoxviruses is in general relatively unaffected by environmental conditions, compared with that of many other viruses. The focus of work on the resistance of vaccinia and variola viruses to physical and chemical agents was quite different: with vaccinia virus the practical objectives were either to ensure the viability and potency of stored vaccine preparations or to

produce an effective inactivated vaccine; with variola virus interest was centred on epidemiological parameters such as its viability in droplet nuclei and the persistence of infectivity in scabs and on fomites.

### Vaccinia Virus

The heat resistance of vaccinia virus, prepared in various ways and exposed to different temperatures, was of major importance in the development of efficient vaccination programmes (see Chapter 11). Glycerolated liquid vaccine, while relatively stable at refrigerator temperature for a few weeks, was quickly inactivated at higher temperatures, especially if exposed to sunlight.

Kaplan (1958) studied the inactivation of vaccinia virus at various temperatures ranging from 50 °C to 60 °C. There was an initial rapid fall in infectivity to  $10^{-5}$  or  $10^{-6}$  of the original titre, followed by inactivation of the residual virus at a much slower rate. Perhaps this phenomenon provides an explanation for the successful long-distance transportation of vaccinia virus that took place from time to time during the 19th century (see Chapter 6). The persistent infectivity was not due to the selection of genetically resistant virus, but was shown by Woodroffe (1960) to be attributable to some change that occurred during the storage of concentrated preparations of virus in the liquid state. The infectivity of freshly prepared suspensions of partially purified vaccinia virions suspended in McIlvaine's buffer was completely destroyed within 60 minutes at 55 °C and within 90 minutes at 50 °C.

Camus (1909), working in France, and later Otten (1927) in Batavia (Jakarta) showed that crude vaccine dried slowly *in vacuo* over sulfuric acid, and stored *in vacuo*, was much more stable than liquid vaccine. Such preparations were used in the French colonies in Africa and for the elimination of smallpox in the Netherlands East Indies (Indonesia) in the late 1930s (see Chapter 8). However, the material was difficult to reconstitute, it was often heavily contaminated with bacteria, and there was a good deal of variation between batches. Subsequently, freeze-drying, which had long been used on a laboratory scale for preserving and transporting viruses and bacteria, was developed on a commercial scale for smallpox vaccine (see Chapter 7). Such material was very stable; Kaplan (1969) reported

that an early production batch of freeze-dried vaccine withstood storage at 45 °C for at least 6 years without loss of potency.

Other methods of inactivation of vaccinia virus were relevant mainly in relation to efforts to produce an inactivated virus vaccine (Turner et al., 1970; see Chapters 3 and 7). Most workers found heating to be unsuitable, as it destroyed antigenicity. Other methods of inactivation that were investigated included ultraviolet irradiation, which had the disadvantage that a small overdosage severely damaged antigenicity (Kaplan, 1969), and formaldehyde, which also damaged antigenicity (Amies, 1961). Photodynamic inactivation with methylene blue (Turner & Kaplan, 1968) and gamma irradiation (Marennikova & Macevič, 1975) appeared to inactivate infectivity with little effect on antigenicity.

### Variola Virus

Periodic assays showed that in temperate climates smallpox scabs could retain infectivity at room temperature for several years. Downie & Dumbell (1947a) recovered variola major virus from crusts stored at room temperature, in the dark or in daylight, for up to 1 year; Wolff & Croon (1968) recorded the persistence of viable alastrim virus in scabs kept in envelopes in a laboratory cupboard for over 13 years. The potential significance of these findings in relation to a possible return of smallpox is discussed in Chapter 30; of more immediate concern to the smallpox eradication programme was the degree to which viability might persist in some tropical countries in which variolation was still practised during the 1970s. Huq (1976) investigated the persistence of viable variola major virus in scabs maintained at various temperatures and relative humidities through 16 weeks of the hot season in Bangladesh (late May to mid-July). Her results are summarized in Table 2.11. The initial titre was  $10^{8.3}$  plaque-forming units. Infectivity fell off rapidly at 35 °C, but at 4 °C viable virus was still present after 16 weeks, both at a relative humidity of 60–62% and in a desiccator (relative humidity, <10%). At ambient temperature the relative humidity affected survival, virus persisting in a viable state for 8 weeks at high humidity and for 12 weeks at low humidity. These results confirm the observation of MacCallum & McDonald (1957) that virus viability was adversely affected by both high

temperatures and high relative humidity. Since these conditions prevailed in most of the countries in which endemic smallpox still occurred in the 1970s, prolonged survival of viable virus did not seem to pose a major long-term threat. However, virus could remain viable for long enough for fomites to present at least a short-term problem, especially in temperate climates.

The foregoing discussion relates mainly to the persistence of the viability of variola virus in scabs in relation to the threat that this might have posed to the eradication programme. One advantage of the heat resistance of variola virus was that it made possible the shipment of swabs and scabs from endemic countries to the WHO collaborating centres in Moscow and Atlanta, in which diagnostic

laboratory studies could be carried out. Vesicle fluid or scab material was mailed in special containers, and although such transmission often took 2 weeks or longer, electron microscopy almost always revealed positive results in cases of smallpox, and chick embryo inoculation was often successful.

An epidemiologically important aspect of the resistance of variola virus to environmental conditions, discussed at greater length in Chapter 4, was its viability in droplets and droplet nuclei under various conditions of temperature and humidity. Short-term (60-minute) experiments showed that variola virus was relatively resistant in aerosols, and viability was only slightly less persistent at high relative humidities (Mayhew & Hahon, 1970). In other experiments, using vaccinia virus as a model, Harper (1961) found that over a longer time interval, viability in aerosols was greatest at low temperatures (10.5-11.5 °C) and low relative humidity (<50%). The adverse effect of high relative humidity was greater at higher temperatures (Table 2.12). If, as is likely, this property also applies to variola virus, it has implications in relation to contact infection and the seasonal fluctuations in the incidence of smallpox, which was more common in the colder and drier months of the year (see Chapter 4).

### SPECULATIONS ABOUT THE ORIGINS OF VARIOLA VIRUS

The elucidation of the history of smallpox over the last 2000 years, which is attempted in Chapter 5, involves much speculation, and alternative interpretations are possible for most of the ancient "plagues" that have been accepted by some authorities as outbreaks of

smallpox. Suggestions as to how smallpox arose as a disease of humans are even more a matter of guesswork.

### The Diversity and Specificity of Viruses of Man

There are some 20 well-characterized families of viruses of vertebrates, 18 of which contain one or more viral species that can infect man (White & Fenner, 1986). No less than 13 of these families include species which can be maintained in man as the sole vertebrate host; many of these viruses are specific for man and do not cause natural self-perpetuating infections in other vertebrates. On the other hand, each of these 13 families contains species of viruses that cause natural infections in vertebrates other than man. Among the family Poxviridae, 8 viral species, belonging to 4 different genera, can cause infections of man, but only 2 species—variola virus and molluscum contagiosum virus—are specifically human pathogens. For every specifically human virus the question of origins relates to how long ago, in the course of biological evolution, did the viral species in question exhibit the capacity to be maintained indefinitely by human-to-human (or proto-human-to-protohuman) spread.

### Requirements for Human-to-Human Transmission

#### General principles

Whether or not a virus can be maintained indefinitely by passage from person to person in populations of various sizes depends on: (1) certain characteristics of the virus, notably its capacity to undergo antigenic change; (2) characteristics of the pathogenesis of the infection, especially the quality of the immune response and whether persistent infection or recurrence of infectivity occur; and (3) characteristics of the population biology of the host, notably the rate of accession of new susceptible subjects (Fig. 2.11). Viruses such as the herpesviruses, which exhibit persistent infection and recurrent infectivity, can be maintained in very small populations, even though they provoke a long-lasting immune response and circulate in a population of long-lived animals. However, viruses such as variola virus, which do not undergo antigenic change sufficient to overcome the

Fig. 2.11. Approximate sizes of populations required for maintaining the endemicity of several specifically human viral diseases. (From Black, 1982.)

immunity of previously infected hosts and which do not cause persistent infection with recurrent infectivity, will survive only in populations sufficiently large or with a sufficiently rapid turnover rate to ensure that some susceptible individuals are always likely to be infected. In this connection the turnover rate is affected by mobility and contact between population groups.

#### The case of variola virus

It was possible to eradicate smallpox in the 20th century because it was a disease that could persist only by transmission from one susceptible human being to another. In the absence of an alternative animal host, and lacking the capacity to cause endogenous recurrent disease in an individual who had been infected, the virus could persist in a population only if enough susceptible humans were constantly available to maintain a continuous chain of infection. Studies of the closely analogous situation in measles, both in the cities of the British Isles and the USA

(Bartlett, 1957, 1960) and in the islands of the Pacific (Black, 1966), suggest that a population of not less than 300 000–500 000 is necessary to sustain endemic measles. If, in the case of smallpox we reduce this to perhaps 200 000 because it spread less rapidly than measles, the disease could be sustained indefinitely in man as the sole host only after the introduction of irrigated agriculture—some 10 000 years ago—had initiated the first great population explosion.

What then could have been the source of the virus that caused the disease that has been recognized as smallpox for 2000–3000 years? Two possibilities exist: either man acquired the virus from some animal host in which it could be maintained because the animal occurred in larger numbers and had a much shorter generation time than had man, the hunter-gatherer; or else humans (or perhaps protohumans) had long been the host of an ancestral "variola virus" which produced a different sort of disease, one that could persist in small groups of hunter-gatherers, and subsequently changed its behaviour in the human host. We shall now examine these possibilities.

#### **Possible Derivation of Variola Virus from another *Orthopoxvirus***

Variola virus is usually thought to have been derived from a closely related virus of some other animal, possibly an animal that was domesticated early and thus maintained close relations with early man. There are 4 orthopoxviruses known today that infect animals with which ancient man was or may have been in contact: camelpox, cowpox, ectromelia and monkeypox viruses.

##### *Camelpox virus*

Camelids evolved in the Americas and spread to Asia and North Africa some 3 million years ago. They would certainly have been hunted by early man, but were probably domesticated after sheep and cattle, perhaps some 5000 years ago. As it now occurs, camelpox virus is highly host-specific; its genome map is distinctive and quite different from that of variola virus.

##### *Cowpox virus*

This virus can infect a variety of different species of animal. It is probably maintained in

nature in rodents, but occasionally infects man, cattle, cats and other domestic animals. Its genome is the largest of all the orthopoxviruses but deletion mutations occur commonly, producing progeny with smaller genomes. None of the strains of cowpox virus that have been examined has a genome that looks at all like that of variola virus.

##### *Ectromelia virus*

Now known only as the cause of mousepox in laboratory mice, ectromelia virus has a narrow host range and a distinctive genome map. Its original natural host was probably some field rodent.

##### *Monkeypox virus*

Since human monkeypox is clinically so like smallpox (see Chapter 29), it is natural to think of it as a possible progenitor of smallpox; or perhaps it would be more correct to think of a "proto-monkeypox" virus as having given rise to a "proto-variola" virus. The molecular biology of such a transformation is discussed in Chapter 30; suffice it to say that the DNA of monkeypox virus is no more similar to that of variola virus than is any other known orthopoxvirus DNA (see Fig. 2.7, 2.9 and 2.10).

At the present time monkeypox virus appears to occur naturally only in the tropical rain forests of central and western Africa. There is no evidence that human populations large enough to support the evolution and persistence of a virus with the characteristics of variola virus ever occurred in this part of the world in prehistoric times; 4000–5000 years ago populations of that size appear to have occurred only in the great river valleys of Egypt, the Fertile Crescent, the Indian subcontinent and eastern Asia. A disease recognizable as smallpox was present in Egypt in 1157 BC (if Ramses V did indeed die of smallpox) and in India and China perhaps as long as 2000 years ago. How could monkeypox virus, in its original form or as an evolving variola virus, move from western or central Africa to the Nile valley? The Sahara, as we now know it, would appear to have constituted an impossible barrier. But that was not always the case. Palaeoclimatic studies of Africa are in their infancy, but there is good evidence that the Sahara and the Sahel were much less arid in the period 9000 BC to 2000 BC than they are now, and supported popula-

tions of elephants and giraffes as well as ancient man (McIntosh & McIntosh, 1981). Further south, this savanna-like country merged into tropical rain forests that supported a rich fauna then, as they do now. In this kind of climatic regime, it is not impossible to conceive of the movement of newly evolving variola virus from areas far to the south and west into the Nile valley, where it might have persisted in the large human population of the Middle Kingdom.

### Variola Virus as the Descendant of an *Orthopoxvirus* of Early Man

The other possibility is that variola virus had long existed among protohuman primates and our early ancestors. To explain its persistence in such small populations and the later emergence of smallpox as we know it, it is necessary to invoke the concepts of "K-selection" and "r-selection" ( $K$  refers to the carrying capacity of the environment;  $r$  to the maximal intrinsic rate of natural increase) used by ecologists to help to understand physiological and evolutionary adaptations, especially of insects and plants (Pianka, 1970; Southwood et al., 1974).

The human population was in a stage of  $K$ -selection until irrigated agriculture, which was developed some 10 000 years ago in the river valleys of Asia and northern Africa, vastly increased the potential human food supply and thus initiated the human population explosion that continues to this day—a situation in which  $r$ -selection became dominant. This change was accompanied by new evolutionary opportunities for viruses. During the phase of  $K$ -selection of their host, microbial parasites, including viruses, were also subject to  $K$ -selection. Only agents associated with prolonged or recurrent infectivity—for example, the human herpesviruses—could survive without recourse to an animal host. However, when the population became much larger and the annual input of susceptible individuals increased, viruses which produced diseases that were infectious for a brief period only, and that rendered the host immune thereafter, could survive and evolve. Under such conditions the viruses would be subjected to strong  $r$ -selection.

It is not difficult to accept this overall concept as being relevant to the evolution of the common respiratory and enteric viruses of man. It could be applied to smallpox in the

following way: Man, the hunter-gatherer, and his forebears were hosts of a specifically human (or protohuman) "proto-variola" virus, which was able to persist in their small populations because infected individuals remained infectious for a long time. When irrigated agriculture allowed man to escape from the restrictions of  $K$ -selection, new opportunities existed for specifically human viruses, since susceptible populations were then large enough to support viruses that caused diseases which were infectious for a short period and rendered the host immune to reinfection. If a mutant arose from the "proto-variola" virus that multiplied much more prolifically ( $r$ -selection) and caused an acute generalized infection, it would soon replace its progenitor "proto-variola" virus wherever the human population was large enough. The result might be variola virus and smallpox. This hypothesis would have received strong support if the hypothetical "proto-variola" virus had been found among any of the hunter-gatherer populations in areas in which the population was until recent times subject to  $K$ -selection—the Americas, Australia and southern Africa. The behaviour of smallpox on first contact with these populations indicates that no such "proto-variola" virus existed there and this hypothesis remains unproved and unlikely.

### Conclusions

We have to conclude that at present we do not know how, when or where variola virus originated. An origin from an orthopoxvirus of some other animal seems probable—and perhaps monkeypox virus may be suggested as the most likely candidate, on the grounds that it causes a disease in humans that is very like smallpox, rather than because of a particularly close resemblance between the DNAs of the respective viruses. Smallpox appears to have occurred for some 3000 years as a disease with the same characteristics as it exhibited up to the time of its eradication in 1977. The ultimate answer to its origin could come from studies of the nature and variability of the genomes of variola virus and other orthopoxviruses. However, with the eradication of smallpox, research on variola DNA is unlikely to be extensively pursued. Even if the problem is in principle soluble, we may never arrive at an answer.

## INTRODUCTION

Because of its distinctive clinical picture, described in the previous chapter, smallpox has been recognized as a disease entity for many centuries. Its control by deliberate intervention, at first by variolation, then by vaccination, began long before such measures were adopted for any other disease. Likewise, knowledge of the virus that produced the disease and those that were used to control it, variola and cowpox or vaccinia viruses respectively, is as old as the relatively new science of virology. The particles that cause these two diseases were seen with the microscope, and then by electron microscopy, before any other viruses had been visualized, and their chemical composition was analysed earlier than that of any other animal virus. The family to which they belong, now called Poxviridae, was correctly categorized before any other viral family, and the genus *Orthopoxvirus*, whose members are the causative agents of smallpox, vaccinia and the several related

diseases with which this book is less directly concerned, was delineated as early as any other viral genus as the "variola-vaccinia subgroup" of the poxvirus group.

This chapter outlines the historical development and current state of knowledge of the orthopoxviruses, based primarily on studies with vaccinia virus. Much of the material presented will be of special interest to biologists, but it includes topics of greater complexity and of a more technical nature than can be readily understood by the otherwise informed general reader. However, the authors consider that it is important in this book to endeavour to embrace the full scope of currently available knowledge of the orthopoxviruses. For the virologist the account will appear unbalanced, since the intention is to limit it to providing the virological background that is necessary to understand how the body responds to infection with these viruses, how the clinical diagnosis can be confirmed by laboratory studies, and what other related agents may pose threats to man,

### The Nature of Viruses in General and Poxviruses in Particular

Viruses form a distinct group of agents, which differ fundamentally from cellular microorganisms. The infective particle, known as the virion, is inert; it proceeds to a dynamic phase only after it enters a susceptible cell and loses enough of its outer protective layers to allow its genetic material to be transcribed and translated. The inert poxvirion is the largest of all virions and its genetic material, a single molecule of double-stranded DNA, is among the largest of all viral genomes. Poxviruses differ from most other DNA viruses in that they replicate in the cytoplasm rather than in the nucleus of susceptible cells. To accomplish this, they have a battery of enzymes not found in other DNA viruses, including a viral DNA-dependent RNA polymerase which transcribes messenger RNA from the viral DNA.

confuse the diagnosis or give rise to problems in interpreting ecological data. To do this it will be necessary to describe some features of the orthopoxviruses, such as their structure, the composition of their genetic material and their behaviour in experimental animals, in some detail, but it is not necessary to provide a detailed analysis of the complex events of the replication cycle, a feature which has always been of central interest to virologists.

### CLASSIFICATION AND NOMENCLATURE

The internationally accepted classification of viruses is based primarily on the morphology of the viral particle (virion) and the nature and structure of the viral nucleic acid. As the largest of all viruses, the virions of poxviruses were the first to be seen with the microscope.

#### Development of Knowledge of the Structure of Poxvirions

As early as 1886, Buist (see Gordon, 1937) reported that he had seen what must have been the virions of vaccinia virus in stained smears, although he regarded them as spores. Calmette & Guérin (1901) used the rabbit to assay batches of vaccine lymph and in the course of this work they observed that the lymph contained numerous minute refractile particles which they suggested might be the "virulent elements". These observations were confirmed by Prowazek (1905), an expert microscopist, who found that they could be stained by Giemsa's method, and revived the

term "elementary bodies", originally introduced by Chaveau (1868) and used until recently to describe the virions. Paschen (1906) used a modified Loeffler's flagellar stain and championed the belief that the elementary bodies of vaccinia virus thus made visible with the microscope were the infective particles; they were later also called "Paschen bodies" in recognition of Paschen's extensive work in this field (Plate 2.1). Negri (1906) had shown that the infectivity of vaccine lymph would remain after the lymph had been passed through a filter that held back bacteria, but final proof that the elementary body was indeed the infectious entity was not provided until Ledingham (1931) showed that antisera produced against vaccinia or fowlpox viruses would simultaneously and specifically agglutinate the particles and neutralize the infectivity of the homologous but not the heterologous virus.

**Plate 2.1.** "Elementary bodies" (virions) of vaccinia virus. Bar = 1  $\mu$ m. Imprint of a rabbit cornea infected with vaccinia virus, prepared and stained by Paschen in 1906.

BY COURTESY OF S. DALES AND C.F. ROBINOW

Further analysis of the structure of poxvirions has depended on the use of the electron microscope with virions treated in various ways. Enzymatic digestion was used to demonstrate the existence of a substructure within the brick-shaped virions (Dawson & McFarlane, 1948). In a series of classical studies, Peters (1956), using enzymatic digestion with deoxyribonuclease and metal shadowing, demonstrated the major viral components and designated them as the outer membrane, the lateral bodies and the core. Thin sections of infected cells have been particularly valuable in elucidating the morphogenesis of the virions of vaccinia virus. Negative staining, combined with a variety of methods of degrading the virion, has been useful in analysing the substructure of vaccinia virions (Easterbrook, 1966; Medzon & Bauer, 1970) and in demonstrating the distinctive surface structure of the outer membrane. The negative staining method, first used for poxviruses by Nagington & Horne (1962), was the cornerstone of the laboratory diagnosis of smallpox as it was developed during the Intensified Smallpox Eradication Programme.

### The Nucleic Acid of Poxviruses

Following the development of methods of purification of vaccinia virus by differential centrifugation, workers at the Rockefeller Institute of Medical Research in New York showed that the virions contained 5.6% DNA (Hoagland et al., 1940) but no RNA (Smadel & Hoagland, 1942). The DNA was shown to be double-stranded, with a guanine + cytosine content of 36–37% (Jöklík, 1962), and subsequent studies showed that it occurred as a single linear molecule with a relative molecular mass of about 123 million comprising 186 000 base pairs (186 kbp).

### Classification of Poxviruses

Traditional classifications of diseases were based on symptoms, and certain diseases of man, cow, horse, sheep and pig were grouped together as "poxes" because they were characterized by pocks on the skin. Several of these diseases were caused by poxviruses, but the deficiencies of a classification of causative agents based on signs and symptoms were highlighted by the inclusion of chickenpox

(caused by a herpesvirus) and "the great pox" (syphilis—caused by a spirochaete) in the same category as smallpox.

By examining sections of poxvirus-infected tissues, pathologists came to recognize cytoplasmic inclusion bodies as characteristic of poxvirus infection (Guarnieri, 1892), although for many years they were regarded as protozoa. Gradually, however, the significance of the minute particles seen in stained smears was appreciated, and by the 1920s Aragão (1927) grouped together, as belonging to one family, the viruses of "myxoma, smallpox, molluscum contagiosum, epithelioma of fowls, etc.". Subsequently, Goodpasture (1933) formally proposed that vaccinia-variola, fowlpox, horsepox, sheep-pox, goat-pox, swinepox and molluscum contagiosum viruses should be grouped together as the genus *Borreliota*. Some years later, Buddingh (1953), using particle morphology and the character of the inclusion bodies as well as symptomatology and host range as the criteria, suggested a classification which, as far as it goes, accords with current ideas, except that all viruses with mammalian hosts were included in the same subgroup.

Writing on behalf of the Poxvirus Subcommittee set up by the Sixth International Congress for Microbiology, Fenner & Burnet (1957) produced a short description of the poxvirus group that has remained the basis of subsequent classifications in respect of the criteria used and the subdivisions adopted, although the names they proposed for species were not accepted, and the status of categories (genus, species, etc.) has been changed. With a view to bringing order and international agreement into viral classification and nomenclature, an International Committee on Nomenclature of Viruses was established in 1966, at the Ninth International Congress for Microbiology in Moscow. This Committee, whose name was subsequently changed to the International Committee on Taxonomy of Viruses, is now accepted as the international adjudicator on viral taxonomy and nomenclature (Matthews, 1983); the currently accepted classification of the poxviruses of vertebrates is set out in Table 2.1.

### Chordopoxvirinae: the Poxviruses of Vertebrates

The basic features of members of the subfamily Chordopoxvirinae are the large size

Table 2.1. The classification of poxviruses of vertebrates

Family	Poxviridae
Subfamily	Chordopoxvirinae
Genera	<i>Orthopoxvirus</i> (vaccinia)
(prototype species)	<i>Avipoxvirus</i> (fowlpox)
	<i>Capripoxvirus</i> (sheep-pox)
	<i>Leporipoxvirus</i> (myxoma)
	<i>Parapoxvirus</i> (milker's nodule)
	<i>Suipoxvirus</i> (swinepox)
	Unclassified molluscum contagiosum, tanapox

and characteristic ovoid or brick-like shape of the virion and the possession of a genome consisting of a single linear molecule of double-stranded DNA with a relative molecular mass that ranges, for different genera, between 85 million for *Parapoxvirus* and 185 million for *Avipoxvirus*. The virions of all members incorporate several enzymes, including a DNA-dependent RNA polymerase. These enable poxviruses to replicate in the cytoplasm of infected cells.

### The Genus *Orthopoxvirus*

The subfamily Chordopoxvirinae includes many viruses that are related to each other only in the general properties just listed. The genus with which this chapter is concerned, *Orthopoxvirus*, is much more homogeneous, as befits its lower taxonomic status. Table 2.2 lists the names, host ranges and geographical distribution of what, on the basis of their biological properties and genome structure, are 9 distinct species of *Orthopoxvirus*. All these species show extensive serological cross-reactivity, by both *in vitro* tests (gel diffusion, complement fixation, haemagglutination inhibition, etc.) and by neutralization tests

and cross-protection in laboratory animals; indeed the last two tests form the basis for the tentative allocation of a poxvirus isolate to the genus *Orthopoxvirus*.

Traditionally (e.g., Baxby, 1975, 1977b), species of *Orthopoxvirus* have been named primarily on the basis of the host animal from which they were derived, and identified on the basis of a range of biological characteristics in laboratory animals. The most important indicators were the host range, the morphology of the pock and the ceiling temperature at which it was produced on the chorioallantoic membrane of the developing chick embryo. The situation was changed by the discovery by Müller et al. (1978) and Esposito et al. (1978) that the DNAs of representative strains of each of several different species of *Orthopoxvirus* showed distinctive patterns after digestion with restriction endonucleases. With a larger number of strains of several different species, Mackett & Archard (1979) showed that all species of *Orthopoxvirus* shared a large conserved central part of their genomes. Analysis of the DNA structure now provides an alternative and more fundamental primary criterion for the classification of orthopoxviruses (see Fig. 2.6).

### Recognized Species of *Orthopoxvirus*

Historical features relating to the discovery and recognition of the accepted species of *Orthopoxvirus* are summarized below.

#### *Variola virus*

This virus, which caused human smallpox, has a restricted host range in laboratory

Table 2.2. Species of the genus *Orthopoxvirus*

Species	Animals found naturally infected	Host range in laboratory animals	Geographical range: natural infections
Variola	Man (infection now eradicated)	Narrow	Formerly world-wide
Vaccinia	Numerous: man, cow, <sup>a</sup> buffalo, <sup>a</sup> pig, <sup>a</sup> rabbit <sup>a</sup>	Broad	World-wide
Cowpox	Numerous: cow, man, rats, cats, gerbils, large felines, elephants, rhinoceroses, okapis	Broad	Europe (and Turkmenian SSR)
Monkeypox	Numerous: monkeys, great apes, anteaters, squirrels, man	Broad	Western and central Africa
Ectromelia	Mice, shrews	Narrow	Europe
Camelpox	Camels	Narrow	Africa and Asia
Taterapox	<i>Tatera kempi</i> (a gerbil)	Narrow	Western Africa
Raccoonpox	Raccoons	?Broad	USA
Uasin Gishu disease	Horses (from a wildlife reservoir host)	Medium	Eastern Africa

<sup>a</sup> Infected from man.

animals. Early reports of its transfer to animals are difficult to interpret, but monkeys were used quite early (Zuelzer, 1874) and extensively (e.g., Brinckerhoff & Tyzzer, 1906). Variola virus was subsequently grown in the rabbit cornea and a test developed to differentiate it from chickenpox virus (Paul, 1915). Later it was grown in chick embryos (Torres & Teixeira, 1935), and North et al. (1944) and Downie & Dumbell (1947b) showed that the pocks produced by variola virus on the chorioallantoic membrane were sufficiently distinctive to allow its differentiation from vaccinia and cowpox viruses. A detailed account of the virology of variola virus is presented later in this chapter.

#### *Vaccinia virus*

Though a different species of *Orthopoxvirus* from Jenner's "variola vaccinae", vaccinia virus is the agent that has been most widely used for vaccination. Baxby (1977c, 1981) has summarized speculations about its origins (see Chapter 7). Many strains are supposed to have been derived from variola virus (Wokatsch, 1972; see Chapter 11). However, when experiments were carried out under conditions which precluded the possibility of cross-infection with vaccinia virus, "transformation" of variola virus into vaccinia virus could not be demonstrated (Herrlich et al., 1963).

There are many strains of vaccinia virus with different biological properties, although all have many features in common, such as their wide host range, rapid growth on the chorioallantoic membrane and distinctive genome maps. Since vaccinia virus has a broad host range and has been very widely used for many decades, accidental infections of domestic animals were not uncommon when human vaccination was practised on a large scale (see Table 2.7). Sometimes serial transmission occurs naturally in such animals (cows, buffaloes, rabbits).

In the history of smallpox eradication, vaccinia virus is second only to variola virus in its importance. It is also the "model" orthopoxvirus, with which the vast majority of laboratory investigations of viruses of this genus have been performed. Aspects of its virology are further discussed later in this chapter and its use in the prevention of smallpox is described at length in Chapters 6, 7 and 11.

#### *Cowpox virus*

For many years before the time of Jenner, cowpox had been recognized as a disease of cows that was transmissible to man, producing ulcers on the cow's teats and on the milker's hands. The distinction between cowpox and vaccinia viruses was first made by Downie (Davies et al., 1938; Downie, 1939a,b). A number of strains of *Orthopoxvirus* recovered from diverse animals in zoos and circuses, as well as from rodents (see Chapter 29), have now been recognized as being very similar in both their biological properties and their genome maps to the strains of cowpox virus that have been recovered from cows and man; all of these strains belong to the cowpox virus species. Since cowpox virus was so important in the history of smallpox control (see Chapter 6) and causes occasional infections in man (see Chapter 29), its properties are discussed at greater length later in this chapter.

#### *Monkeypox virus*

This virus was first recovered from cynomolgus monkeys that had been captured in Malaysia in 1958 and shipped by air to Copenhagen, where they were housed together for several weeks before the disease was recognized (Magnus et al., 1959; see Chapter 29). Several other isolations of the virus were subsequently made from captive primates in Europe and North America between 1960 and 1968 (Arita & Henderson, 1968). In 1970 monkeypox virus was isolated from a case of a disease in a human being in Zaire diagnosed clinically as smallpox (Ladnyj et al., 1972; Marennikova et al., 1972a); human monkeypox has now been recognized as a rare zoonosis occurring in several countries in western and central Africa.

Monkeypox virus infection in monkeys has been used as a model for the study of the pathogenesis of smallpox (see Chapter 3). The properties of monkeypox virus, the clinical and epidemiological features of human monkeypox, and its ecology in Africa are discussed in Chapter 29.

#### *Ectromelia virus*

Infectious ectromelia, later called mousepox, was described in the United Kingdom by Marchal (1930), and the virus was subsequently recovered from laboratory mice in

many parts of the world (Fenner, 1982). Serological studies (Kaplan et al., 1980) suggest that voles may be a reservoir host of ectromelia virus in nature. Mousepox has been extensively used as a model system for studies relevant to the pathogenesis and immunology of smallpox (see Chapter 3). Ectromelia virus does not produce disease in man (Fenner, 1949a).

#### *Camelpox virus*

This virus shares several biological properties with variola virus and was originally described as being "extremely closely related" to variola virus (Baxby, 1972). However, it behaves differently in cultured cells (Baxby, 1974) and has a distinctive genome structure (Fig. 2.6). The camel appears to be the only natural host. It was first isolated in tissue culture by Ramyar & Hessami (1972) and its affinities with the genus *Orthopoxvirus* were recognized by Baxby (1972). Extensive studies in Somalia during the Intensified Smallpox Eradication Programme confirmed that it did not cause disease in man (Ježek et al., 1983).

#### *Taterapox virus*

This virus was recovered from pooled liver/spleen material obtained from small naked-soled gerbils (*Tatera kempi*) captured in Benin in 1964 (Kemp et al., 1974). It was studied by Gispén (1972) and Huq (1972), and characterized as a species of *Orthopoxvirus* by Lourie et al. (1975), who described it as "like variola minor virus" and speculated about its possible role in the long-term survival of variola virus. However, it has a distinctive genome map (see Fig. 2.6), which shows the usual features of orthopoxvirus DNA.

Nothing is known of its natural history, and little except what is shown in Table 2.3 is known of its biological properties. Taterapox virus may be one of several orthopoxviruses responsible for the high proportion of positive results obtained in orthopoxvirus haemagglutination-inhibition tests carried out on sera derived from a variety of wild animals captured in tropical rain forest regions in Africa (see Chapter 29).

#### *Raccoonpox virus*

The only indigenous orthopoxvirus yet recovered from the Americas, this virus was

isolated from raccoons in the eastern USA (Alexander et al., 1972) and characterized as a distinct species of *Orthopoxvirus* by Thomas et al. (1975). Its genome could not be mapped by methods used for other orthopoxviruses, since only about half the *HindIII* restriction endonuclease fragments cross-hybridized with those of other orthopoxviruses (Esposito & Knight, 1985), indicating a much more distant relationship than that found between other orthopoxviruses.

#### *Uasin Gishu disease virus*

This is an African orthopoxvirus recognized only by the fact that it causes papular lesions in horses in parts of Kenya (Kaminjolo et al., 1974a,b). It appears to be a virus enzootic in African wildlife, and if more widely distributed it could complicate ecological studies of monkeypox virus by blurring the serological picture.

### CHARACTERISTICS SHARED BY ALL SPECIES OF ORTHOPOXVIRUS

Having shown the way in which early studies of the morphology of poxvirus particles led to a classification of the family and the designation of the genus *Orthopoxvirus*, it is necessary now to outline current views on the structure and chemistry of these viruses. The vast majority of such studies were carried out with vaccinia virus, but they apply, with minor variations, to all orthopoxviruses.

#### Morphology of the Virion

Fig. 2.1, which is based on electron microscopic studies of vaccinia virus using thin sections, negative staining and freeze-etching, represents the virion as consisting of four major elements: core, lateral bodies, outer membrane and, as an inconstant component, an envelope. The well-defined central core (Plate 2.2C and D) contains the viral DNA, and on each side of the core there is an oval mass called the lateral body. The core and lateral bodies are enclosed within a well-defined "outer membrane", which has a characteristic ribbed surface structure (Plate 2.2A and Fig. 2.1), and is composed of a large number of surface tubules (Plate 2.3). The viral DNA within the core, which is associ-

Fig. 2.1. The structure of the vaccinia virion. Right-hand side, section of enveloped virion; left-hand side, surface structure of non-enveloped particle. The viral DNA and several proteins within the core are organized as a "nucleosome". The core has a 9-nm thick membrane, with a regular subunit structure. Within the virion, the core assumes a dumb-bell shape because of the large lateral bodies. The core and lateral bodies are enclosed in a protein shell about 12 nm thick—the outer membrane, the surface of which consists of irregularly arranged tubules, which in turn consist of small globular subunits. Virions released naturally from the cell are enclosed within an envelope which contains host cell lipids and several virus-specified polypeptides, including the haemagglutinin; they are infectious. Most virions remain cell-associated and are released by cellular disruption. These particles lack an envelope so that the outer membrane constitutes their surface; they also are infectious.

ated with at least 4 different proteins, is maintained in a superhelical configuration, and appears to occur in globular structures interconnected by DNA-protein fibres, resembling the nucleosome structures of eukaryotic chromatin (Soloski & Holowczak, 1981). Virions released spontaneously from cells are often enclosed within a lipoprotein envelope (Plate 2.2B) which contains the vaccinia haemagglutinin and several other virus-specific polypeptides (Payne & Norrby, 1976; Payne, 1978). Virions released by cellular disruption are infectious but lack an envelope (Appleyard et al., 1971); their outer surface is then composed of the outer membrane.

The envelope probably plays a role in the spread of virions within the animal body and thus in pathogenesis (see Chapter 3). More important in the context of smallpox control is the suggestion that the low protective power of inactivated vaccines (see Chapters 3

and 11) is due in part to the fact that they consist of inactivated non-enveloped virions (Boulter & Appleyard, 1973), whereas live virus vaccines produce envelope proteins in the process of replication.

### Antigenic Structure

The large and complex virions of orthopoxviruses contain a very large number of polypeptides, each of which probably contains several epitopes (antigenic sites). Much modern virological research is concerned with the structure and function of the viral polypeptides, their location in the virion and the processes by which they are produced during viral replication. Such research will undoubtedly illuminate our understanding of the biology of orthopoxviruses and the way in which they cause disease, but it is peripheral to the practical problems with which this book is concerned. However, three aspects of the composition of these polypeptides and their antigenic makeup are highly relevant: (1) some antigens show cross-reactivity across the whole subfamily Chordopoxvirinae; (2) many antigens, including those important in generating a protective immune response, show cross-reactivity within the genus *Orthopoxvirus*; and (3) some antigens are species-specific.

#### *Antigens common to the subfamily Chordopoxvirinae*

Investigations carried out some years ago using crude chemical and serological methods showed that one or several antigens were shared by all members of the subfamily that could be studied. Takahashi et al. (1959) demonstrated that both myxoma-immune sera and vaccinia-immune sera reacted with members of the *Orthopoxvirus*, *Leporipoxvirus*, and *Avipoxvirus* genera when tested by complement-fixation and immunofluorescence tests. Woodroffe & Fenner (1962) were able to demonstrate group cross-reactivity by complement-fixation or immunofluorescence tests only when they extracted the so-called "NP antigen" (Smadel et al., 1942) from myxoma or vaccinia virus. Such preparations reacted with antisera to a wide range of poxviruses, belonging to 5 different genera.

Ikuta et al. (1979) reinvestigated the problem, using radioimmunoprecipitation, and

**Plate 2.2.** Electron micrographs of vaccinia virions. **A:** Non-enveloped virion, showing the surface tubular elements that make up the outer membrane. **B:** Enveloped virion, as released from the infected cell and found in extracellular medium. **C:** Thin section of non-enveloped virion showing the biconcave core (c) and the two lateral bodies (lb). **D:** Viral core, released after treatment of virions with Nonidet 40 and mercaptoethanol. Bar = 100 nm. (**A** from Dales, 1963; **B** from Payne & Kristensson, 1979; **C** from Pogo & Dales, 1969; **D** from Easterbrook, 1966.)

demonstrated that among the 30 antigenic polypeptides found in one-dimensional gels prepared from cells infected with vaccinia, cowpox and Shope fibroma viruses (the last-named belonging to the genus *Leporipoxvirus*) there were 4 which showed cross-reactivity between the orthopoxviruses and Shope fibroma virus. There were, as expected, additional cross-reactive polypeptides shared by vaccinia and cowpox viruses but not found in fibroma virus.

These subfamily serological cross-reactions are not without practical importance. If methods that detect many different antigen-antibody reactions are used in serological surveys of animal sera for evidence of orthopoxvirus infection (e.g., immunofluorescence, enzyme-linked immunosorbent assay (ELISA), or radioimmunoassay), positive reactions may be produced by agents other than orthopoxviruses, such as tanapox virus, i.e., a positive result may mean only that the donor

of the serum has been infected with a member of the subfamily Chordopoxvirinae.

#### *Cross-reactions between orthopoxviruses*

An unknown agent having been identified as a poxvirus, perhaps by electron microscopy of infected tissues (see, for example, the work of Kaminjolo et al. (1974a) with the virus of Uasin Gishu disease), the next step in its identification as an orthopoxvirus depends on various kinds of serological cross-reactions between it and a recognized member of the genus, such as vaccinia virus. Three kinds of reactions are employed: (1) cross-protection in laboratory animals or cross-neutralization of infectivity; (2) demonstration of an orthopoxvirus-specific haemagglutinin; and (3) analysis of soluble antigens in agar gels by precipitation in gel, immunoelectrophoresis or radioimmunoprecipitation reactions. Both cross-protection and cross-neutralization are

strictly genus-specific, and orthopoxviruses are the only members of the family Poxviridae that produce a haemagglutinin.

**Cross-protection.** This is the classical way of demonstrating the relatedness of poxviruses as members of the same genus. It was first performed as a deliberate experiment by Jenner (1798), when he inoculated James Phipps with pus from a case of smallpox—2 months after having inoculated him with cowpox virus obtained from Sarah Nelmes. Cross-protection remains the most important test for membership of the genus *Orthopoxvirus*; it can now be supplemented by comparisons of DNA maps.

**Cross-neutralization of infectivity.** Cross-protection tests depend on a range of immune reactions, cell-mediated as well as humoral. A more limited but more flexible test, since it can be performed in eggs or cultured cells, is the neutralization of infectivity of the homologous and selected heterologous viruses by convalescent serum. This test has been widely used for demonstrating the relatedness of various orthopoxviruses (e.g., Downie & McCarthy, 1950; McNeill, 1968).

“Protective antigens”—i.e., those which elicit the production of neutralizing antibodies to orthopoxviruses—fall into two classes: the surface tubular elements of the outer membrane of the virion and some of the virus-specific antigens in the viral envelope. A protein with a relative molecular mass of 58 000 polymerizes to form the surface tubules that are a prominent feature of the outer membrane of vaccinia virions (Plate 2.2A). These surface tubular elements have been isolated from virions in a pure form (Plate 2.3); they elicit neutralizing antibody to non-enveloped but not to enveloped virions and block the neutralizing capacity of antibody to non-enveloped virions (Stern & Dales, 1976; Payne, 1980).

Other protective antigens are located in the viral envelope, which is found only in virions that are released naturally from cells. Analysis of the differences between the polypeptides of non-enveloped virions and enveloped virions by one-dimensional polyacrylamide gel electrophoresis (Payne, 1978) showed that the envelope contained 10 additional polypeptides (9 of which were glycosylated) with relative molecular masses of between 20 000 and 210 000.

Antibody to the isolated envelopes neutralized the infectivity of enveloped forms of

vaccinia virus, as demonstrated by the “anti-comet” test of Appleyard et al. (1971) (see Chapter 3, Plate 3.10), whereas antibody to inactivated non-enveloped virions did not do so (Payne, 1980). It is not known which of the envelope polypeptides are involved in neutralization reactions.

**Haemagglutination-inhibition tests.** Of all the poxviruses, only those of the genus *Orthopoxvirus* produce a haemagglutinin. This is active only on certain kinds of chicken cells (Nagler, 1942) and, with ectromelia virus, on mouse cells (Mills & Pratt, 1980). The agglutinability of chicken cells is genetically determined; White Leghorns produce agglutinable red blood cells whereas several other strains of chicken (e.g., Plymouth Rock) do not (Suzuki et al., 1955). It was the detection of haemagglutination that could be inhibited by vaccinia-immune serum that led Burnet & Boake (1946) to suggest that ectromelia virus was a member of the genus *Orthopoxvirus*. More recently, the production of the characteristic haemagglutination has been important in suggesting that raccoonpox virus (Thomas et al., 1975), taterapox virus (Lourie et al., 1975) and the virus of Uasin Gishu disease (Kaminjolo et al., 1974b) belong to this genus.

Early studies showed that vaccinia haemagglutinin was a lipoprotein, composed of a viral antigen and a lipid which was responsible for attachment to the red blood cell (Burnet, 1946; Stone, 1946; Chu, 1948). Active haemagglutinin can be reconstituted from these two components after they have been separated by ether/ethanol extraction (Smith et al., 1973). From the time of its discovery, the haemagglutinin was regarded as separable from the virus particle (Burnet & Stone, 1946) and this was the orthodox view for many years. However, the numerous investigations that demonstrated the dissociation of haemagglutinin and virion were carried out with preparations obtained by the disruption of infected cells. With the demonstration that vaccinia virions were sometimes released in an enveloped form, the problem was reinvestigated by Payne & Norrby (1976) and Payne (1979), who demonstrated that vaccinia haemagglutinin is the dominant glycoprotein in the envelopes of vaccinia virions and also occurs in the membranes of cells infected with vaccinia virus, where it can be demonstrated by haemadsorption tests. When cells are disrupted, the non-enveloped virions are readily separable from the haemagglutinin by centrifugation.

**Plate 2.3.** Purified surface tubules of the outer membrane of vaccinia virus. Bar = 100 nm. On the left is the upper part of an electropherogram of virion polypeptides run side by side with a preparation of the surface tubules that migrates as a single band of 58 K. (From Stern & Dales, 1976.)

Haemagglutinins of different species of *Orthopoxvirus* cross-react extensively. Using sera from immunized chickens, McCarthy & Helbert (1960) found no evidence of specificity for homologous antigens. On the other hand, Fenner (1949a) found that homologous titres were always higher than heterologous, when comparing vaccinia and ectromelia haemagglutinins. Infection with ectromelia virus of mice previously vaccinated with vaccinia virus resulted in a reversal of titres of inhibition of the respective haemagglutinins.

**Analysis of soluble antigens.** As already described, there are a few soluble antigens that show cross-reactivity throughout the subfamily Chordopoxvirinae. However, there are very many more that show cross-reactivity within each genus. The principal uses of methods of identifying soluble antigens (gel diffusion and radioimmunoprecipitation) are twofold: (1) in analysing the dynamics of viral replication and the detailed structure of the orthopoxvirion; and (2) in comparing different mutants, strains and species of *Orthopoxvirus*. In the present context, demonstration of extensive cross-reactivity between a known orthopoxvirus and a new poxvirus isolate would provide strong evidence that the latter belonged to this genus.

### Composition and Structure of the Viral DNA

The genome of all members of the genus *Orthopoxvirus* is a single linear molecule of double-stranded DNA, with relative molecular masses varying for different species from 110 million to 140 million, comprising between 165 kbp and 210 kbp. Orthopoxvirus DNAs contain no unusual bases and the guanine + cytosine content is very low—about 36%. The relative molecular mass of the DNA of different strains of vaccinia virus varies between 118 million and 125 million.

Vaccinia virus DNA behaves in an anomalous way when it is denatured. Instead of separating, the two sister strands form a large single-stranded circular molecule, being attached at or near each end of the genome by covalent links (Geshelin & Berns, 1974). For the most part the DNA sequences in the vaccinia genome are unique, but the two terminal fragments cross-hybridize with each other (Wittek et al., 1977) and with the termini of other species of orthopoxvirus (Mackett & Archard, 1979). This inverted terminal repetition is about 10 kbp long in the strains of vaccinia virus used by Wittek, but

Fig. 2.2. Schematic representation of the DNA of vaccinia virus (Lister strain). **A:** Linear double-stranded molecule with terminal hairpins and inverted repeats (not to scale). When denatured it forms a very large single-stranded circular molecule. **B:** Cleavage sites of restriction endonucleases *Hind*III (vertical lines) and *Sma*I (arrow). The asterisk indicates the fragment containing the thymidine kinase gene, which is used in experiments with vaccinia virus as a vector for hybrid vaccines. **C:** Each 10 kilobase pair (kbp) terminal portion includes 2 groups of tandem repeats of short sequences rich in adenine-thymine.

its length varies considerably in other orthopoxviruses. For example, in a series of mutants of cowpox virus studied by Archard et al. (1984), the length of the terminal repetition varied from 4.5 kbp to 41 kbp, almost 20% of the entire genome. Within each terminal repeat of vaccinia virus there are 30 reiterations of a 70-bp sequence arranged in tandem and grouped into 2 discrete groups of 17 and 13 units (Wittek & Moss, 1980; Fig. 2.2). Garon et al. (1978) visualized the terminal repetition by electron microscopy, which showed that the opposite ends of each strand are complementary to each other. The continuity of the DNA chain around the single-strand hairpin loop at the end of the molecule was shown in a variety of ways, culminating in the determination of the base sequence by Baroudy et al. (1982).

The analysis of vaccinia DNA and of the differences between DNAs derived from different species, strains and mutants of orthopoxviruses entered a new phase with Wittek's determination of a physical map of vaccinia virus DNA by analysis of the fragments produced when it was treated with various restriction endonucleases (Wittek et al., 1977).

Restriction endonuclease analysis provides a most important tool for the study of orthopoxviruses. On the one hand it opened the way to the cloning of selected fragments of orthopoxvirus DNA in *Escherichia coli*, ultimately encompassing the whole of the viral DNA, with all its implications for the examination of the molecular biology of viral replication. On the other hand, the demonstration by Mackett & Archard (1979) that a large central part of the genome of all

orthopoxviruses is very similar makes restriction endonuclease analysis a powerful method for taxonomic comparisons of different orthopoxviruses. In this book the composition of the DNA, as determined by restriction endonuclease analysis, has been accepted as the ultimate criterion for allocating viruses to species within the genus *Orthopoxvirus*, and as the technique of choice for examining the affinities of various strains and mutants that have been recovered from time to time.

### Non-genetic Reactivation

Poxviruses exhibit a unique kind of reactivation of "killed" virus. It was first observed by Berry & Dedrick (1936) with the leporipoxviruses myxoma virus and fibroma virus and was called viral "transformation". However, it is now known to be a general property of the poxviruses of vertebrates. Poxviruses that have been inactivated by methods which do not damage their DNA can be reactivated; any active member of the subfamily Chordopoxvirinae appears to be able to reactivate any other member of that subfamily inactivated by, for example, heating (review: Fenner, 1962). Reactivation depends on single cells being co-infected with the two viruses concerned, and is essentially an example of complementation. Heating destroys the core-associated DNA-dependent RNA polymerase; the active virus provides this enzyme, or enzymes that release DNA from the cores of both the active and the reactivated viruses. Non-genetic reactivation is a useful tool for obtaining hybrids between orthopoxviruses.

### Restriction Endonuclease Mapping of Orthopoxvirus DNAs

Restriction endonucleases are bacterial enzymes that cleave double-stranded DNA at sites which are determined by sequences of 4 or 6 nucleotides. To compare the DNAs of different orthopoxviruses, a few enzymes have been selected for which there are only a few cleavage sites along the whole length of the viral genome. After digestion, the mixture of DNA fragments is separated by electrophoresis in agarose gels, stained and photographed to show the bands of DNA arranged in accordance with their molecular weights. Cross-hybridization with selected radioactively labelled fragments of other orthopoxvirus DNAs makes it possible to identify relationships between different orthopoxviruses and arrange the fragments in a linear order along the viral genome (see Fig. 2.6).

To simplify comparisons between the maps of different orthopoxvirus species, strains and mutants, a method of computer-aided analysis of the cleavage sites described by Gibbs & Fenner (1984) has been used. Briefly, the maps of different DNAs are aligned along selected highly conserved cleavage sites. All other cleavage sites for particular enzymes, on all the DNAs under study, are then compared and scored as present, absent, or "impossible" (the DNA molecule may be too small to accommodate the cleavage site in question). The figures thus obtained are analysed by the computer program MULCLAS (Lance & Williams, 1967) and the results expressed as a dendrogram indicating degrees of dissimilarity. The absolute values depend on the number of attributes (separate cleavage sites) in the group of DNAs under study, so that different dendrograms may give quite different figures for the "index of dissimilarity" between the same DNA molecules, if different restriction enzymes or groups of enzymes are used. With orthopoxvirus DNAs such analysis may place undue weight on the effects of internal deletions and transpositions, but it offers a rough method of comparing strains that is better than visual comparisons of the DNA maps (see Fig. 2.7).

More detailed analysis of the orthopoxvirus DNA is carried out by incorporating selected fragments into plasmids and then into *Escherichia coli*. Large quantities of the selected fragments can then be produced and analysed by further digestion with restriction endonucleases for which there are numerous cleavage sites, or particular pieces of DNA can be sequenced.

### CHARACTERIZATION OF ORTHOPOXVIRUSES BY BIOLOGICAL TESTS

Morphology is useful for classification only at the subfamily level, since only the genus *Parapoxvirus* can be unequivocally distinguished from the other genera of Chordopoxvirinae by the morphology of the virions, as seen in negatively stained preparations. Cross-protection and neutralization tests make it possible to allocate a poxvirus to the genus *Orthopoxvirus*. Allocation of an orthopoxvirus to a particular species depends on the use of several biological and chemical tests, respectively to categorize the effects of the virus in various animals and cell systems and to define the nature of its DNA and polypeptides.

In this book attention will be concentrated on the attributes of the 4 orthopoxviruses that were of most significance in relation to

smallpox and its eradication: variola, vaccinia, cowpox and monkeypox viruses. More detailed descriptions of the biology of these viruses, and that of the other species of *Orthopoxvirus*, can be found in Fenner et al. (1987).

### Lesions in Rabbit Skin

Historically, one of the earliest tests which clearly differentiated variola from vaccinia virus was the demonstration that only the latter virus produced lesions in rabbit skin, after either scarification or intradermal inoculation. Subsequent investigations have confirmed the value of this test.

Within the *Orthopoxvirus* genus, there is a correlation between the reaction in rabbit skin (Plate 2.6) and the character of the pocks produced on the chorioallantoic (CA) mem-

c. 1965

**Plate 2.4.** Allan Watt Downie (b. 1901). Formerly Professor of Bacteriology in the University of Liverpool, Downie was a leading worker in the virology and immunology of poxviruses from the late 1930s until the 1970s and made major contributions to our knowledge of cowpox, variola and tanapox viruses. K.R. Dumbell (Plate 2.12) and H.S. Bedson (Plate 2.14) trained under him as graduate students.

brane (see below). Each of 3 species (cowpox, monkeypox and neurovaccinia, including rabbitpox virus) which produce haemorrhagic (ulcerated) pocks on the CA membrane cause large indurated skin lesions with a purple-coloured central area that usually ulcerates before healing. "Dermal" strains of vaccinia virus, which produce small white pocks on the CA membrane, and white pock mutants of cowpox, monkeypox and rabbitpox viruses elicit smaller, pink, nodular lesions. Variola, camelpox and ectromelia viruses produce at most a small papule with transient erythema, which is non-transmissible.

### Pocks on the Chorioallantoic Membrane

All orthopoxviruses produce pocks on the CA membrane, without the need for adaptation by passage. Goodpasture et al. (1932) first cultivated vaccinia virus on the CA membrane and Keogh (1936) demonstrated that dermal and neurotropic strains of vaccinia virus produced readily distinguishable kinds of pocks, which were white and haemorrhagic (ulcerated) respectively. In contrast, variola virus produces small white pocks on the CA membrane, which can be readily distinguished from those of vaccinia virus (North et al., 1944). Cowpox virus was first cultivated

on the CA membrane by Downie (1939a), who showed that it produced bright-red haemorrhagic pocks, clearly distinguishable from those of both vaccinia and variola viruses (Plate 2.5).

Monkeypox virus was not recognized until 1958, when Magnus et al. (1959) demonstrated pocks, which "resembled closely those described for variola virus", on CA membranes inoculated with material from pustular lesions on infected monkeys. Later studies (Marennikova et al., 1971; Randle & Sayeed, 1972) showed that the pocks of monkeypox virus are distinguishable from those of other orthopoxviruses; like those of variola virus, they are small, but instead of being dense, white and opaque, they are pink and have an ulcerated, slightly haemorrhagic surface.

The pocks produced by species that elicit opaque white pocks on the CA membrane are usually uniform in character; all pocks on a membrane are similar. On the other hand, species or strains of virus that produce ulcerated pocks (cowpox, monkeypox, and the neurovaccinia and rabbitpox strains of vaccinia virus) regularly produce white pock mutants (Downie & Haddock, 1952; Fenner, 1958; Gemmell & Fenner, 1960; Dumbell & Archard, 1980), which usually differ from the strains producing red pocks in several other biological characteristics, such as the type of lesion in the rabbit skin and, often, their lethality for mice and chick embryos. Vaccinia virus passaged for commercial vaccine production may contain virions producing both white and grey ulcerated pocks; the passage of vaccinia virus by intracerebral or intratesticular inoculation of rabbits or mice usually selects for mutants which produce ulcerated, haemorrhagic pocks on the CA membrane.

### Ceiling Temperature

When carrying out experiments on the growth of several different viruses on the CA membrane, Burnet (1936) noticed that ectromelia virus produced pocks at 37 °C but not at 39.5 °C. This finding was developed by Bedson & Dumbell (1961), who introduced the concept of the "ceiling temperature" as the highest temperature at which pock formation on the CA membrane would occur. The ceiling temperature has proved to be a useful criterion for distinguishing between different species of *Orthopoxvirus* (Table 2.3). It has also

### Appearance of Orthopoxvirus Pocks on the Chorioallantoic Membrane

The most useful laboratory test for distinguishing between species of *Orthopoxvirus* is the appearance of pocks on the CA membrane. Unlike plaques in cultured cells, which result from the direct interaction between cells and virus, a third component enters into the appearance of pocks—namely, leukocytes and erythrocytes delivered to the site via the bloodstream. Basically, a pock is a greyish-white focus, varying in diameter from 0.4 mm to 4 mm, according to virus species. It is produced by a combination of hyperplasia of the ectodermal layer of the CA membrane and the infiltration of cells into the mesodermal layer. Sometimes, as with variola virus, the surface of the pock is glossy white, owing to pronounced hyperplasia of the ectoderm; sometimes, as with monkeypox virus, the superficial layer ulcerates and there is a superficial haemorrhage into the crater. The pocks of cowpox virus are bright red, because very little leukocytic infiltration occurs and there are capillary haemorrhages into the pock.

Expression of the "characteristic" pock phenotype is influenced by the concentration of pocks and the temperature of incubation. Expression of the "red" pock phenotype is enhanced when the pocks are semiconfluent or confluent. Also, at higher temperatures pocks tend to be greyish-white and non-ulcerated, whereas at lower temperatures some species (but not variola virus) produce pocks with an ulcerated, haemorrhagic centre. For example, at 37 °C camelpox virus produces small pocks very similar to those of variola virus (Mayr et al., 1972), but at 35 °C it produces pocks with a haemorrhagic centre (Marennikova et al., 1973). Likewise, at 37 °C monkeypox virus produces white pocks very like those of variola virus (Magnus et al., 1959), whereas at 35 °C the pocks are ulcerated and haemorrhagic (Marennikova et al., 1971).

proved useful in distinguishing between variola major and alastrim viruses (Nizamuddin & Dumbell, 1961; Dumbell & Huq, 1986). Cultured cells can also be used for measuring ceiling temperatures (Porterfield & Allison, 1960).

Different species of orthopoxviruses recovered from geographically separate places and at different times usually have the ceiling temperature characteristic of the species. However, in the laboratory ceiling temperature mutants, which are then usually called temperature-sensitive (*ts*) mutants, can be readily obtained by appropriate selection methods. Sambrook et al. (1966) and Dales et al. (1978) have recovered large numbers of different *ts* mutants of vaccinia virus. Conversely, Dumbell et al. (1967) obtained two thermo-efficient strains of variola major virus by serial passage at incrementally higher temperatures.

### Lethality for Mice and Chick Embryos

The response to infection depends on the age of the animal and its genetic background, the route of inoculation, and the viral species

or strain. Variola virus is much less lethal for mice and chick embryos than the other species of *Orthopoxvirus* that can infect man (Table 2.3).

### Growth in Cultured Cells

Most orthopoxviruses can be grown in one or another kind of cultured cell and assayed by plaque counts in suitable susceptible cells. Species which have a wide host range among intact animals (e.g., vaccinia, cowpox and monkeypox viruses) tend to grow to high titres and in a wide range of cells, and to produce lytic plaques. Species with a restricted host range, such as variola virus, replicate in a narrower range of cells and often produce hyperplastic foci (see Plate 2.13). However, on serial passage, adaptation occurs readily and may involve change to a more lytic plaque. Monolayers infected with viruses that produce hyperplastic foci usually yield much less virus than those infected with viruses that produce lytic plaques, since most cells in the monolayer remain uninfected. Differential growth capacity in particular cell lines (e.g., the rabbit cell line RK 13 and pig embryo

**Plate 2.5.** The appearance of pocks on the chorioallantoic membrane produced by various species of *Orthopoxvirus* that infect man. Monkeypox virus pocks photographed after incubation for 3 days at 35 °C; all others after 3 days at 36 °C. **A:** Variola major virus. **B:** Vaccinia virus (Lister strain). **C:** Monkeypox virus (Copenhagen strain). **D:** Cowpox virus (Brighton strain).

**Plate 2.6.** Lesions produced in the rabbit skin 5 days after the intradermal inoculation of doses of  $10^5$  pock-forming units of various species of *Orthopoxvirus*. Ectromelia (ECT), taterapox (TAT) and camelpox (CAM) viruses produce no lesions and variola (VAR) virus elicits only a slight erythema. Monkeypox (MPX) and cowpox (CPX) viruses produce large indurated lesions with a purple centre that often ulcerates. The response to vaccinia virus (VAC) varies with the strain; "dermal" strains usually produce a distinct red indurated nodule and neurovaccinia a lesion like that produced by cowpox virus.

**Plate 2.7.** Cytoplasmic inclusion bodies in cells infected with orthopoxviruses. **A:** B-type inclusion bodies (Guarnieri bodies) in hyperplastic ectodermal cells of the chorioallantoic membrane, in a pock produced by variola virus. Note that the surface of the pock is intact and there are no erythrocytes in the ectoderm, although they are present within a vessel in the mesoderm. (Eosin and methyl blue stain.) **B:** B-type (pale-red, irregular) and A-type (large eosinophilic, with halo) inclusion bodies in ectodermal cells of the chorioallantoic membrane, in a pock produced by cowpox virus. There are also a number of nucleated erythrocytes in the ectoderm and free in the mesoderm, and the surface of the pock is ulcerated. **C:** Section of the skin of a patient with haemorrhagic-type smallpox, showing Guarnieri bodies, and free erythrocytes below an early vesicle. (Haematoxylin and eosin.)

A. W. DOWNIE

kidney cells) may be useful in distinguishing between variola and monkeypox viruses when these viruses are first inoculated into such cells (see below); however, adaptation occurs readily.

Since the viral haemagglutinin is inserted into the cytoplasmic membrane of infected cells, haemadsorption can be used to detect orthopoxvirus infection in cultured cells. Different patterns of haemadsorption have proved useful in distinguishing between isolates of variola virus from different parts of the world (see below).

### **Inclusion Bodies**

Two kinds of inclusion bodies occur in the cytoplasm of cells infected with orthopoxviruses, which Japanese investigators (Kato et al., 1959) have distinguished as A-type and B-type (Plate 2.7). B-type inclusions are the sites of viral replication and are produced by all orthopoxviruses. A-type inclusions are strongly eosinophilic and are found only in cells infected with cowpox, ectromelia and raccoonpox viruses.

### **Comparison of Biological Characteristics of Different Species**

Although a good deal of variation in biological behaviour occurs between different strains of the orthopoxviruses that have been the most carefully studied, certain characteristics appear to be regularly associated with each species (Table 2.3). Most of the characteristics listed are usually or invariably found with recently isolated strains of all species; some appear to be very stable, whereas others can be altered by the deliberate selection of mutants or by serial passage at high concentration.

## **VIRAL REPLICATION**

Viral replication is a central focus of virology, yet it is largely peripheral to the understanding of smallpox and vaccination, with which this book is concerned. We shall therefore restrict the description of the replication of poxviruses to a simplified diagram (Fig. 2.3), and describe briefly aspects that are relevant to the pathogenesis and immunology of smallpox and vaccinia—namely, the initia-

tion of infection, assembly and release of progeny virions and changes in infected cells. The reader interested in a more detailed account of poxvirus replication should consult Moss (1985) or Fenner et al. (1987).

### **Adsorption, Penetration and Uncoating**

The first stage of viral infection consists of adsorption to and penetration of host cells. Enveloped and "naked" orthopoxvirus particles, although both infectious, behave differently. The outer membrane of the non-enveloped particle fuses with the plasma membrane at the surface of the cell, or within a vacuole formed by invagination of the plasma membrane, thus releasing the viral core into the cytoplasm. Enveloped virions are adsorbed more rapidly and efficiently, which explains why they play an important role in the spread of infection, both in cultured cells and in intact animals (see Chapter 3).

### **Assembly and Maturation**

Electron microscopic analysis of thin sections of infected cells suggest a sequence of developmental events, shown diagrammatically in Fig. 2.4. The initial stages of virion formation occur in circumscribed granular electron-dense areas of the cytoplasm. The first morphologically distinct structures are crescents (or cupules in three dimensions) consisting of a bilayer membrane with a brush-like border of spicules on the convex surface and granular material adjacent to the concave surface (Plate 2.8). The spicules are thought to give the membrane its rigid convex shape, which determines the size of the immature viral particles. Ultimately the spicules appear to be replaced by the surface tubular elements of the outer membrane. The immature viral membranes appear circular (or spherical in three dimensions) with a dense nucleoprotein mass embedded in a granular matrix. The nucleoprotein appears to enter the immature envelopes just before they are completely sealed. It is unclear whether the majority of the proteins destined to form the mature particle, which includes proteins of the core membrane and the lateral bodies and many viral enzymes, are enclosed within the membrane of the immature particle or injected simultaneously or sequentially after its

Table 2.3. Biological characteristics of recognized species of *Orthopoxvirus*

Fig. 2.3. The replication cycle of vaccinia virus. Both enveloped and non-enveloped particles are infectious but differ in their attachment to cells and mode of entry (not shown). The sequence of events is (1) attachment and entry. (2) uncoating I, whereby the outer membrane is removed by cellular enzymes, leaving the core, (3) immediate early transcription from DNA within the core by the viral transcriptase, leading to the production of early enzymes which include the enzyme that produces (4) uncoating II and release of the viral DNA into the cytoplasm. Early transcription continues and simultaneously (5) DNA replication occurs, after which (6) late transcription occurs from the newly synthesized DNA, followed by translation, and cleavage, glycosylation and phosphorylation of some of the late proteins. Morphogenesis (7) is illustrated in more detail in Fig. 2.4. (From Moss, 1985.)

development. The additional morphological changes by which the immature particle is reorganized to become a mature virion require continuing protein synthesis. Although DNA replication does not involve the activity of the cell nucleus, assembly is very inefficient in cells lacking functional nuclei.

### Release

In the majority of the vaccinia-virus/cell systems that have been studied, most of the mature progeny virions remain cell-associated. Cell-associated virions are released when the cell undergoes necrosis, and they may infect contiguous cells, within a solid organ or in a cell monolayer, without ever being exposed to an extracellular environment. This occurs by the recruitment of contiguous cells into polykaryocytes (Dales & Siminovich,

1961), as well as by the necrosis of the infected cell, and is well demonstrated by the development of plaques in the presence of neutralizing antibody in the overlay medium (see Chapter 3, Plate 3.10).

Release of virions from the plasma membrane of the intact cultured cell also occurs. Tsutsui (1983) observed a simple budding process in FL cells, but more commonly mature "naked" virions acquire a double membrane envelope in the vicinity of the Golgi apparatus (Ichihashi et al., 1971; Payne & Kristensson, 1979; Plate 2.9A) and migrate to the cell surface, apparently under the influence of cytoplasmic microfilaments (Hiller et al., 1979). At the cell surface the outer of these two membranes fuses with the plasma membrane, releasing enveloped virions (Plate 2.9C and D). This process also occurs in mice infected with vaccinia virus (Payne & Kristensson, 1985).

Fig. 2.4. Diagram of a cell representing the morphogenesis of vaccinia virions. The viroplasm, or viral "factory", visualized in stained cells as the B-type inclusion body, is first seen at 2.5 hours, cupules first appear at 4 hours, and some are completed as immature particles at 6–8 hours. From 8 hours onwards mature particles appear, maturation occurring within the membrane of the immature particles, which loses its spicules and acquires surface tubules. Processes involving envelopment and release are not shown. (From Moss, 1985.)

The efficiency of egress by envelopment is affected both by the type of host cell and by the strain of virus used; RK 13 cells give a high yield of enveloped virions, especially with certain strains of vaccinia virus (Payne, 1980). Routine electron microscopy of material from smallpox pustules and scabs rarely revealed enveloped virions (J. H. Nakano, personal communication, 1982). In cells infected with cowpox virus, most mature virions are usually associated with A-type inclusion bodies (see Plate 2.10).

### Cellular Changes

Within one or two hours of infection, so-called "toxic" changes may occur in the infected cells, which in monolayer cultures become rounded and retract from each other (Fig. 2.5). New antigens occur on the cytoplasmic membrane very early (Ueda et al., 1972), and by the 4th hour there is cytological evidence of viral replication; basophilic areas appear in the cytoplasm—the viral "factories" of Cairns (1960). Eventually gross changes

occur in the cells; depending on the particular virus–host cell combination there may be an aggregation of cells into hyperplastic foci, adjacent cells may fuse to form large polykaryocytes, or cell necrosis and rupture may occur, with release of the cell-associated virions.

### Inclusion bodies

The appearances of the inclusion bodies found in orthopoxvirus-infected cells is shown in Plate 2.7. B-type inclusion bodies are irregular in shape, stain rather weakly with most histological stains and are found in all poxvirus-infected cells. They were first described in cells infected with variola and vaccinia viruses by Guarnieri (1892) and are often eponymously known as "Guarnieri bodies". It is now clear that these B-type inclusions are the cellular sites of poxvirus replication. A-type inclusion bodies, on the other hand, are usually spherical, stain brilliantly with eosin, and are characteristic of cells infected with ectromelia, cowpox and raccoonpox viruses but are not found in infection with the other orthopoxviruses. Depending on the genetic nature of the virus, A-type inclusions may contain many mature virions or be devoid of them (Plate 2.10; Ichihashi & Matsumoto, 1968). They usually appear late in infection and are not associated with viral replication.

### Changes in the cell surface

Some of the earliest changes, and the most significant in relation to the immune response, are the virus-induced alterations in the plasma membranes of infected cells. Some virus-coded antigens are expressed on the surface of the cell within 2 hours of infection (Ueda et al., 1972; Amano et al., 1979); other polypeptides which develop late in infection, including the haemagglutinin and several other envelope glycoproteins, are also incorporated into the plasma membranes of infected cells (Payne, 1979). The development of membrane-associated haemagglutinin can be followed by haemadsorption tests, which have been used in the analysis of differences between variola major and alastrim viruses (Dumbell & Wells, 1982; Dumbell & Huq, 1986; see Table 2.4). Some of these viral antigens promote cell fusion and thus cell-to-cell spread of virions.

**Plate 2.8.** Viral morphogenesis. **A:** Infected cell showing viral "factory" area with immature particles on right; mature naked intracellular virions on left. Bar = 1000 nm. **B:** "Factory" area showing the "caps" (cupules) of developing immature viral particles. Bar = 100 nm. (**A** from Payne & Kristensson, 1979; **B** from Dales & Siminovich, 1961.)

### CHARACTERIZATION OF ORTHOPOXVIRUSES BY CHEMICAL METHODS

Species, strains, and mutants of orthopoxviruses can be characterized by analyses of their DNAs, using restriction endonuclease digestion, or by an examination of gene products (polypeptides) applying serological tests or separation in polyacrylamide gels.

#### Comparison of Viral DNAs

##### *Differences in DNAs of different species*

The DNAs of orthopoxviruses range in size from 165 kbp for variola virus to 210 kbp for cowpox virus. The larger differences, i.e., between species, are reproducible but there is some strain variation within each species. As will be described later, deletion mutants occur quite commonly and often involve the loss of substantial fragments of DNA from one or the other end of the genome.

As illustrated in Fig. 2.2, the opposing terminal fragments of the DNAs of most orthopoxviruses contain long terminal repeats, hence they cross-hybridize. Variola virus is an exception, in that it lacks an obvious inverted terminal repeat, so that opposite termini do not cross-hybridize (Mackett & Archard, 1979; Dumbell & Archard, 1980). One end of variola DNA was found to hybridize with termini of the DNAs of other species of orthopoxviruses; the other end hybridized with a subterminal fragment of monkeypox DNA. The absence of a terminal repeat is not absolute; Esposito & Knight (1985) have shown that a very small fragment from the vaccinia DNA terminus that hybridizes well with one end of variola DNA hybridizes weakly with the other end, suggesting that there is a very small terminal repetition, less than 0.5 kbp, in variola DNA.

Major comparative studies of the DNAs of different species of orthopoxviruses have been carried out by Mackett (1981) in the United Kingdom and Esposito in the USA

**Plate 2.9.** Release of enveloped virions by cells of mouse respiratory tract after infection with vaccinia virus. **A:** Acquisition of double membranes in vicinity of Golgi apparatus. **B:** Double-enveloped particles in cytoplasm of cell. **C and D:** Virions with a single envelope after release from cells. bars = 500 nm. (Esposito & Knight, 1985). In this section an attempt is made, using restriction endonuclease maps, to provide the chemical basis for the species designations that are shown in Tables 2.2 and 2.3.

Fig. 2.6 sets out the cleavage sites of the restriction endonuclease *Hind*III in the DNA molecules of strains of each of the 8 species of *Orthopoxvirus* for which such maps are available. Uasin Gishu disease virus DNA has not yet been analysed by restriction endonuclease digestion. Several *Hind*III fragments of raccoonpox virus DNA (the only species of *Orthopoxvirus* yet found to be endemic in the

Americas) cross-hybridize with those of other *Orthopoxvirus* species, but not at all with *Hind*III fragments of DNAs of mammalian poxviruses of other genera (*Leporipoxvirus*, *Parapoxvirus*) found in North America. However, the "map" of raccoonpox virus does not lend itself to comparisons by the computer program used for producing Fig. 2.7. The large central conserved area of all the DNAs that have been mapped is readily apparent in the *Hind*III maps. The close resemblance between the representative strains of particular species (shown in greater detail in Fig. 2.9 and 2.10, and Chapter 29, Fig. 29.1 and 29.4)

Fig. 2.5. Cellular changes seen at various times (logarithmic scale) after infection of a monolayer of cultured cells.

and the differences between species, particularly towards the ends of the molecule, are apparent, but it is difficult to appreciate these quantitatively by visual inspection of restriction maps. The similarities and differences are brought out better by the dendrogram (Fig. 2.7). On the basis of this kind of analysis it is possible to distinguish clearly between all species of *Orthopoxvirus* that have been mapped. Other analyses, involving several strains of each of several species in a single dendrogram (Fenner et al., WHO/SE/80.154), showed that all strains of each species clustered together and species remained clearly separable.

#### *Changes in DNA associated with mutation and recombination*

The foregoing description of the structure and composition of orthopoxvirus DNA may have given the impression that the DNAs of various species are fixed. To some extent this is true; however, minor changes due to mutation occur very frequently and deletion mutations, which are known to occur commonly among the orthopoxviruses with a wide host range (vaccinia, cowpox and monkeypox viruses), can be associated with losses of substantial amounts of viral DNA. Furthermore, different strains and species of *Orthopoxvirus* recombine readily when single cells are subjected to mixed infection, with associated changes in the DNA.

Diversity in DNA molecules may be readily generated within a species, presumably by "autorecombination" during replication. For example, the terminal fragments of vaccinia DNA may become heterogeneous in length

(Wittek et al., 1978), as does the internal junction fragment of white pock mutants of cowpox virus (Archard et al., 1984). These heterogeneities can be eliminated, at least temporarily, by cloning the virus. Indeed, cloning, by the growth of stocks from single pocks or plaques, is an obligatory procedure if stocks of relative genetic homogeneity are required. For example, both Fenner (1958) and Ghendon & Chernos (1964) found that stock preparations of several different strains of smallpox vaccine contained virus that produced mixed pocks (ulcerated and non-ulcerated), which could be separated by cloning.

The most important kind of mutation, from the point of view of the global smallpox eradication campaign, were the white pock mutants of monkeypox virus (see Chapter 30). All orthopoxviruses that produce ulcerated (haemorrhagic) pocks on the CA membrane (cowpox, monkeypox and neurovaccinia strains of vaccinia virus, including rabbitpox virus) produce non-ulcerated (white) pocks with a frequency (from cloned preparations) that varies between 0.1% and 0.01%. In all cases in which several white pocks have been examined, most mutants obtained from a single cloned preparation have been different (Gemmell & Fenner, 1960; Dumbell & Archard, 1980), and the majority of such mutants involve large deletions from one or the other end of the genome, which are often associated with transpositions (Archard et al., 1984; Moyer & Rothe, 1980; Dumbell & Archard, 1980). In spite of these major changes in the amount of DNA, the rest of the genome map is recognizably that of the parental virus (see Chapter 30, Fig. 30.2).

**Plate 2.10.** A-type inclusion bodies produced by cowpox virus. Depending on the genetic characteristics of the strain, the inclusion body may contain large numbers of virions (A), or none at all (B).

### Comparison of Viral Polypeptides

#### *Serological tests*

The earliest methods of comparing the polypeptides of different orthopoxviruses were based on serological tests. All orthopoxviruses show substantial cross-reactivity in tests for neutralization of infectivity, although differences between species and

strains can be demonstrated by absorption tests (Baxby, 1982a). Gel-diffusion tests, which had been shown to distinguish over 20 different antigens in cells infected with rabbitpox virus (Appleyard & Westwood, 1964a), provided an obvious method for attempting the serological differentiation of different species of *Orthopoxvirus*. Using absorbed sera, Gispén & Brand-Saathof (1974) and subsequently Esposito et al. (1977a)

Fig. 2.6. Physical map locations of *Hind*III restriction sites in the DNAs of 8 of the recognized species of *Orthopoxvirus*. Origin of DNAs: Monkeypox (Zaire)—Congo 1970, an isolate from a human case in Zaire; Monkeypox (W. Africa)—Copenhagen, an isolate from monkey, probably originating in West Africa; Taterapox—Benin isolate; Ectromelia—Hampstead strain; Raccoonpox—isolate from Maryland; Cowpox—Brighton strain; Camelpox—Somalia 1248; Variola major—Harvey strain; Alastrim—Butler strain; Vaccinia—Lister and Venezuela strains. (Data from Esposito & Knight, 1985.)

Fig. 2.7. Dendrogram illustrating the similarities and differences between the DNAs for which restriction sites are shown in Fig. 2.6 (except for raccoonpox DNA). Presence, absence or impossibility of sites (because the DNA molecules were too small) were analysed as described by Gibbs & Fenner (1984) using the squared Euclidean metric (number of attributes = 45). The "index of dissimilarity" has no absolute value, but the dendrogram shows that pairs of viruses of the same species (variola, monkeypox and vaccinia) resemble each other more than any other species. Such comparisons are developed with larger numbers of strains of various orthopoxviruses in Fig. 2.9 (variola virus), Fig. 2.10 (vaccinia virus), and in Chapter 29, Fig. 29.1 (monkeypox virus) and Fig. 29.4 (cowpox virus).

demonstrated species-specific antigenic patterns for variola, vaccinia and monkeypox viruses. Maltseva & Marennikova (1976) used absorption in the test well of gel-diffusion plates to distinguish between variola, mon-

keypox, vaccinia and cowpox viruses and showed that isolates from a number of different animals in outbreaks in zoos (okapis, elephants, and various carnivores) reacted like cowpox virus.

Immunofluorescence (Gispen et al., 1974), radioimmunoassay (Hutchinson et al., 1977) and ELISA (Marennikova et al., 1981) have also been used for differentiating variola, monkeypox- and vaccinia-specific antisera, after absorption of the tested sera with homologous and heterologous antigens. All methods were effective in allowing specific diagnoses of monkeypox infection to be made with certain monkey sera. However, while absorption tests are usually successful in demonstrating specific antibodies in high-titre sera, they fail with sera of low titre, such as are often found in sero-epidemiological surveys. Further, sensitive tests such as radioimmunoassay-absorption require antisera to the gamma-globulins of the species under test; such antisera are available for monkeys but not for most other species of wild animal. Thus these tests are unsuitable for routine use with sera from a range of different animals, such as are usually collected during ecological surveys.

*Comparisons of polypeptides in one-dimensional polyacrylamide gels*

Virion polypeptides (Esposito et al., 1977b; Arita & Tagaya, 1980), core polypeptides (Turner & Baxby, 1979) and late intracellular polypeptides (Harper et al., 1979) from several species and isolates of orthopoxviruses have been analysed in one-dimensional polyacrylamide gels. Several differences between species were noted, as were similarities between viruses of uncertain affinities ("Lenny", MK-10-73, buffalopox; see later) and vaccinia virus. However, bands in such gels are identified only by their size and may include monomers and multimers. This disadvantage is lessened when additional information is provided by two-dimensional gels or immunoprecipitation (Ikuta et al., 1979). DNA analysis is at present a simpler and more reliable basis for the identification of orthopoxviruses, but immunoprecipitation may be important in the process of developing species-specific monoclonal antibodies.

## SUMMARY: DISTINCTIONS BETWEEN ORTHOPOXVIRUSES

Poxviruses have larger and more complex virions than most other animal viruses. As a consequence, neutralization tests, which with most viral families are the best method of distinguishing between viral species, are useful only at the generic level, and cross-

neutralization (or cross-protection) provides the most reliable method of allocating an unknown poxvirus to the genus *Orthopoxvirus*.

However, although there is extensive cross-neutralization between all members of the genus, several distinct species exist which differ from one another in a number of biological characteristics, in the size and structure of the genome and in polypeptide composition. Several species are represented by very few independent isolates (ectromelia, camelpox, taterapox, raccoonpox and Uasin Gishu disease viruses), but the properties of the few (or single) isolates of each of these justifies its differentiation as a distinct species. The other 4 species are each represented by many strains, recovered at different times and places.

Variola virus has only been recovered from human subjects and although strains occur which have very different levels of virulence for man, all share many other biological properties and all have very similar genomes.

The other 3 species have wide host ranges. Vaccinia virus has been recovered from a variety of domestic animals and some strains can maintain themselves in nature in rabbits, cows and buffaloes, at least for limited periods of time. However, it seems likely that such infections have originated from human sources. All strains of vaccinia virus share many biological properties and have very similar genomes. Cowpox virus has been recovered from a variety of naturally infected animals, in Europe and the western USSR, but is probably a natural disease of rodents (see Chapter 29). All strains share as characteristic biological properties the production of bright-red haemorrhagic pocks on the CA membrane and the production of A-type as well as B-type cytoplasmic inclusion bodies. Most have larger genomes than those of other orthopoxviruses. Monkeypox virus appears to occur in nature only in western and central Africa, and has been recognized only when infections have occurred in laboratory primates and in man, and once in a wild squirrel. The biological properties of different isolates are very similar, but strains originating from western Africa have rather different genome maps from those recovered in Zaire (see Chapter 29, Fig. 29.1).

## VARIOLA VIRUS

The biological properties of variola virus are enumerated in Table 2.3 and its DNA is

CENTERS FOR DISEASE CONTROL, 1984

**Plate 2.11.** Left: James Hiroto Nakano (b. 1922). The leading American expert on the diagnosis of poxvirus infections. Head of the WHO Collaborating Centre in the Centers for Disease Control, Atlanta, GA, USA, since 1971. Active in much WHO-sponsored research on orthopoxvirus infections and a member of several WHO expert groups on poxvirus infections. Right: Joseph John Esposito (b. 1942). A molecular biologist working at the Centers for Disease Control, Atlanta, GA, USA, who has been responsible for much of the mapping of the DNAs of variola, monkeypox and "whitepox" viruses described in the present chapter and in Chapters 29 and 30.

compared with that of other species of *Orthopoxvirus* in Fig. 2.6. It is a specifically human virus, with a narrow host range in laboratory animals, and can be readily distinguished from other orthopoxviruses that can infect man by the distinctive small white pocks produced on the CA membrane (see Plate 2.5).

### Isolation from Natural Sources

Apart from a few bizarre occurrences, such as the infection of a performing monkey described by Mack & Noble (1970), variola virus has been found in nature only as a specifically human pathogen, and thousands of isolations have been made from infected humans. Reported recoveries of variola virus from animal sources (the so-called "whitepox" viruses), described in Chapter 30, are not regarded as providing an exception to this statement.

### Variola Major and Variola Minor

Observations on outbreaks of smallpox in the USA and South Africa at the end of the 19th century and in the USA and the United Kingdom during the early 20th century led to the recognition that, regardless of the vaccination status of the community involved, some epidemics were associated with a high mortality and others with a low mortality (see Chapter 1). Painstaking epidemiological studies by Chapin & Smith (1932) showed that the novel mild variety of smallpox recognized in the USA early in the 20th century "bred true" and never reverted to the severe variety, either in the USA or when it was transported to other parts of the world. This variety of smallpox was called variola minor and the classical form variola major.

Subsequent studies in different geographical areas showed that strains of variola virus which occurred in various parts of the world differed in their virulence for man, producing

case-fatality rates in unvaccinated individuals that ranged from less than 1% to about 40% (see Chapter 4). However, for practical purposes only two clinico-epidemiological varieties of smallpox were recognized: variola major (case-fatality rates, 5–40%) and variola minor (case-fatality rates, 0.1–2%). Recent laboratory studies of strains of variola minor virus recovered from Africa and the USA (or from countries with variola minor originally derived from the USA) revealed that these two groups of variola minor viruses differ in several characteristics (Dumbell & Huq, 1986); it is convenient to distinguish them by calling the USA-derived strains *alastrim virus* and the other strains *African variola minor virus*.

### Laboratory Investigations with Variola Virus

Because of its danger, variola virus was studied much less than vaccinia virus in the laboratory, especially in recent years, after smallpox had been eliminated from most of the countries in which sophisticated laboratory investigations could be carried out. Laboratory investigations were focused on three aspects: (1) the devising of a diagnostic procedure for the recognition of variola virus; (2) finding correlates in laboratory animals of virulence for man; and (3) during recent years, a comparison of the DNAs of strains of variola virus obtained from different parts of the world and the comparison of the DNAs of variola virus and other orthopoxviruses.

### Pathogenicity for Laboratory Animals

Variola virus was one of the first viruses to be inoculated in laboratory animals, when tests were carried out in monkeys and in cows (in attempts to develop strains of "vaccine"). Subsequent investigations showed that it had a much narrower host range than the other orthopoxviruses that infect man (cowpox, monkeypox and vaccinia viruses), and usually produced smaller or less severe lesions than these viruses in the laboratory animals that were susceptible.

All strains of variola virus produce small white pocks on the CA membrane of developing chick embryos (Plate 2.5); this is the most

ST MARY'S HOSPITAL MEDICAL SCHOOL, LONDON, 1978

**Plate 2.12.** Keith Rodney Dumbell (b. 1922). A leading British virologist who has been involved in studies of variola virus and other orthopoxviruses since 1946. He was head of the WHO Collaborating Centre for Poxvirus Research at St Mary's Hospital Medical School, London, England, from 1969 to 1981, and was a member of the Global Commission and several WHO expert groups on poxvirus infections.

useful laboratory test for differentiating variola virus from other poxviruses in material derived from human subjects. The pocks reach a diameter of 0.3–0.6 mm after 3 days' incubation. They are uniform in size, raised above the surface and have clearly demarcated margins. Unlike camelpox virus, the pocks of which develop a small haemorrhagic centre when the eggs are incubated at 35 °C, the pocks produced by variola virus retain their characteristic opaque white appearance at all temperatures. Experienced laboratory workers can accurately differentiate variola virus from all other poxviruses by this test alone.

Another simple and useful test for differentiating variola virus from monkeypox, vaccinia and cowpox viruses is intradermal inoculation in rabbits, since of these four agents only variola virus fails to produce a large and obvious lesion (Plate 2.6). Dumbell & Bedson (1966) showed that variola virus could be adapted to grow serially in rabbit skin if first passed several times in rabbit kidney cell cultures. It then produced a small nodular lesion at the site of intradermal inoculation, but newly isolated and unadapted strains did not produce transmissible lesions in rabbits, although large doses pro-

duced erythema and a small transient papule at the inoculation site.

Some non-human primates are highly susceptible to infection with variola virus and suffer from a disease with a generalized rash, which may be severe and sometimes lethal in chimpanzees and orang-utans. The symptomatology and pathogenesis of primate smallpox are discussed in Chapter 3.

#### *Tests in cows*

During the 19th century the cow was often inoculated with variola virus, in efforts to obtain new strains of "variola vaccinae" for human vaccination. The old literature contains many claims of success for this procedure, largely from German authors—and claims to the contrary, largely from French authors. Some older accounts, although lacking the precision possible with modern virological methods, provide interesting clues about the claimed "transformation" of variola virus into vaccinia virus by passage in cows. Fleming (1880), in a wide-ranging review, considered that after intradermal inoculation variola virus sometimes produced a small lesion in the skin of the cow, from which passage of material to humans caused inoculation smallpox. He supported French authorities such as Chaveau in saying that variola virus could not be carried in series in cows, although in individual cases early passage inoculations might render them resistant to challenge with cowpox or vaccinia virus.

The most recent experiments in cows are those reported by Herrlich et al. (1963), who inoculated 10 calves with very large doses of variola major virus. Only one reacted with small papules, from which variola virus was recovered but the virus could not be further passaged in cows. Only the animal that reacted was found to be immune when subsequently challenged with vaccinia virus.

#### **Growth in Cultured Cells**

In contrast to its limited host range in laboratory animals, variola virus will grow and produce a cytopathic effect in cultured cells derived from many species (Hahon, 1958; Pirsch et al., 1963). However, it grows best in cells from humans and other primates in which it produces characteristic "hyperplastic" foci. In fact, this appearance (Plate

**Plate 2.13.** Hyperplastic foci produced in HeLa cell monolayers by variola virus (A) and lytic plaques produced by vaccinia virus (B). (Similar large plaques are also produced by monkeypox and cowpox viruses.) Monolayers are in the bottom of Microtiter plates, the wells being 6 mm in diameter. Incubation for 48 hours before staining. (From Kitamura & Tanaka, 1973.)

2.13) is not due to proliferation of the infected cells, but to their aggregation. Because of the low cytopathogenicity of variola virus, infected cells remain in the monolayer and are pushed together by the growing non-infected cells around them (Ono & Kato, 1968). Kitamura (1968) described an assay of variola virus based on counting the hyperplastic foci that develop in HeLa and FL cells (Plate 2.13); in primate cells (Vero and JINET) these foci progress to form small plaques (Tsuchiya & Tagaya, 1970).

Variola virus will replicate and produce a cytopathic effect in continuous-line pig embryo kidney cells (Marennikova et al., 1971), a test which has been used to differentiate it from monkeypox virus. However, Veda & Dumbell (unpublished observations, 1974) found that different strains of monkeypox virus varied in their capacity to grow and produce a cytopathic effect in pig embryo kidney cells; some hardly grew at all, others grew moderately well, but none grew as well as variola or vaccinia viruses.

#### *Haemadsorption*

Some of the haemagglutinin that is produced during orthopoxvirus infections appears in the cytoplasmic membrane of the

**Table 2.4.** Haemadsorption in human embryo fibroblasts incubated at 40 °C for 48 hours after being infected with variola virus at a multiplicity of infection of 1 plaque-forming unit per cell<sup>a</sup>

Variety of smallpox	Sources of isolates	Type of haemadsorption		
		Confluent	Focal	Absent
Asian variola major	United Kingdom	15	4	0
	Pakistan	18	8	0
African variola major	Kenya	25	18	0
	United Republic of Tanzania	2	20	0
	Western Africa	2	39	0
Alastrim	Europe and Brazil	0	5	27
African variola minor	Botswana and Ethiopia	6	15	1

<sup>a</sup> From Dumbell & Huq (1986).

infected cells. When susceptible erythrocytes are added to an infected culture they attach to infected cells, a phenomenon known as haemadsorption. Dumbell & Huq (1986) investigated haemadsorption in human embryo fibroblast cultures which were incubated at 40 °C for 48 hours after inoculation with different strains of variola virus. Haemadsorption was classified as confluent, focal or absent (Table 2.4).

Isolates giving confluent haemadsorption were in the majority among the Asian variola major strains and accounted for over half of the Kenyan isolates. Focal haemadsorption was characteristic of most of the other African isolates, but only a few isolates of either Asian variola major or alastrim viruses reacted in this way. Failure to elicit haemadsorption under the conditions of this test was characteristic of the alastrim virus isolates, and, apart from these, was found only in a single isolate from Ethiopia, which was also like alastrim virus in its failure to produce pocks at 38.3 °C (see Fig. 2.8).

Dumbell & Wells (1982) showed that at 38 °C alastrim virus was inhibited in activities that included the insertion of haemagglutinin into the cell membrane (and hence haemadsorption) and release of virus from the cells, although intracellular maturation proceeded normally; strains of variola major virus and most African strains of variola minor virus showed no such inhibition at 38 °C.

#### *Thymidine kinase activity*

Thymidine kinase is an enzyme which occurs in all cells, since it is essential for DNA metabolism. However, all orthopoxviruses produce a virus-coded thymidine kinase in infected cells (Moss, 1978; Bedson, 1982).

Esposito & Knight (1984) have sequenced the thymidine kinase genes of vaccinia, var-

iola and monkeypox viruses; each differs from the other by some dozen nucleotides (out of 534) and some 5 amino acids (out of 178). Bedson (1982) showed that thymidine kinase produced by each of 11 strains of variola virus (irrespective of geographical origin) was more sensitive to feedback inhibition by thymidine triphosphate than that of any other species of *Orthopoxvirus* (see Table 2.3).

#### **Laboratory Tests for Virulence**

It would clearly have been useful to devise laboratory tests which might have indicated the virulence for man of different strains of

variola virus. Most studies addressed themselves to the problem of differentiating strains that caused variola minor from those that caused variola major. Several tests, outlined below, satisfactorily differentiated strains of alastrim virus derived from the Americas from strains that caused variola major. However, none of these tests distinguished strains of variola minor virus originating in Africa from variola major virus (Dumbell & Huq, 1986).

#### *Pathogenicity for chick embryos*

The first demonstration of a difference between strains of variola major and alastrim viruses in laboratory animals was the finding by Dinger (1956) that variola major virus grew better than alastrim virus in chick embryos. Helbert (1957) then showed that the amounts of variola major and alastrim viruses recovered from the CA membrane in embryos incubated at 35–36 °C were almost the same, but that there was a much higher concentration of virus in the livers of embryos inoculated with variola major virus, and a higher mortality. Dumbell et al. (1961) showed that the mortality was temperature-dependent; both varieties killed embryos at 35 °C but only variola major did so at 37 °C.

Dumbell & Huq (1986) further elaborated Helbert's test of pathogenicity for chick embryos and showed that different strains of variola virus showed a wide spectrum of

response which was not strictly correlated with either virulence or geographical origin. Most strains of Asian variola major virus were of high or moderate pathogenicity. The 8 strains of alastrim virus that were tested were of low or moderate pathogenicity, but strains of variola minor virus from Botswana and Ethiopia showed much the same spectrum of pathogenicity (moderately high to low) as did strains of variola major virus from Kenya. Sarkar & Mitra (1967) reported that different strains of Asian variola major virus differed in their pathogenicity for the chick embryo in eggs incubated at 36 °C.

#### *Ceiling temperature*

Nizamuddin & Dumbell (1961) developed a simple test which reflected the greater temperature sensitivity of growth of alastrim virus compared with variola major virus. A comparison of the numbers of pocks produced on the CA membrane at 35 °C and 38.3 °C allowed an unequivocal distinction to be made between the viruses of variola major and alastrim: variola major virus produced pocks at 38.3 °C but alastrim virus did not. The difference in the temperature sensitivity of viral growth (ceiling temperature) of these two varieties of variola virus could be determined equally well in some lines of cultured cells (Kitamura & Tanaka, 1973).

Subsequent studies confirmed the value of the ceiling temperature as a criterion for

Fig. 2.8. Differences in log titre when incubating each of 196 variola virus isolates from different geographical regions on the chorioallantoic membrane at 35 °C and 38.3 °C. The larger the difference in titre, the greater the sensitivity to a raised temperature (i.e., the lower the ceiling temperature). Each dot is the result of assays of a single isolate; the vertical line shows the median observation for each group of isolates. Alastrim virus = strains of variola minor virus from South America and Europe, originally derived from the Americas. (From Dumbell & Huq, 1986.)

distinguishing alastrim virus (Downie et al., 1963), but strains of variola minor virus of equal or lower virulence from Africa (Botswana, Ethiopia) could not be differentiated from variola major virus by this test (Dumbell & Huq, 1986; Fig. 2.8). One isolate of variola minor virus from Ethiopia stood apart from all others tested in that it resembled alastrim virus in having a low ceiling temperature and failing to produce haemadsorption (Table 2.4). In an earlier study of 61 isolates of variola virus from different geographical locations, including 6 strains from Ethiopia, Shelukhina et al. (1979a) found one Ethiopian strain which resembled alastrim virus in its ceiling temperature and its virulence for mice and chick embryos. The other 5 strains from Ethiopia could not be distinguished from variola major virus by laboratory tests, although they were collected at a time when only variola minor was occurring in Ethiopia.

Initial studies (Bedson et al., 1963; Dumbell & Huq, 1975) suggested that some East African strains that showed lower virulence than Asian variola major were intermediate between variola major and alastrim viruses in their ceiling temperatures. However, attempts to define an "intermediate" strain of variola virus were not successful (Fig. 2.8). Kitamura et al. (1977b), using the temperature sensitivity of the capacity to produce foci in HeLa cells, found that 4 out of 55 strains of variola major virus recovered in India in 1975 were of the "intermediate" level of temperature sensitivity described for some East African strains.

#### Differences in the Virulence of Strains of Variola Major Virus

Another problem, which was studied especially by Sarkar & Mitra (1967, 1968), was whether very severe cases of variola major (haemorrhagic-type and flat-type smallpox, which were almost invariably fatal—see Chapter 1) were caused by more virulent strains of variola major virus than those that caused discrete ordinary-type smallpox. They claimed that strains of variola virus recovered from cases of haemorrhagic-type smallpox were highly virulent for both chick embryos and suckling mice much more frequently than strains derived from discrete ordinary-type smallpox, and suggested that the virulence of the virus was one component in determining the severity of cases of variola major. How-

ever, epidemiological evidence indicates that it was not the most important factor in determining whether a person would suffer from the rare haemorrhagic-type smallpox; physiological factors in the host were probably more important.

On general biological grounds, and by analogy with myxomatosis, a disease in which the assessment of virulence for the natural host was possible by direct testing (see box), it would be expected that a number of strains of variola virus which differed slightly or perhaps substantially in their virulence for man might be circulating at any time in countries in which smallpox was endemic. Because of complexities such as the degree of accuracy of information on cases and/or deaths, the interval since vaccination (if applicable) and age-related differences in case-fatality rates, it was rarely possible to utilize data from smallpox outbreaks other than to determine whether the cause was very mild smallpox (variola minor) or variola major. The significance of apparent differences in case-fatality rates in different outbreaks of variola major were virtually impossible to assess, although most outbreaks in Africa in the 1960s and 1970s had lower case-fatality rates (see Chapters 17–20) than those of variola major in mainland Asia. Unfortunately, except for ceiling temperature tests with alastrim virus, there was no laboratory test of which the results were invariably correlated with virulence for man.

#### Comparison of the DNAs of Strains of Variola Virus

Restriction endonuclease digests of 6 strains of variola virus, derived from outbreaks of variola major and variola minor in Africa, Asia, and Europe, were analysed at the Centers for Disease Control, Atlanta, USA (Esposito et al., 1978; Esposito & Knight, 1985). Physical map locations of the sites of cleavage by the enzyme *Hind*III are compared in Fig. 2.9. Minor differences existed between most strains, but there were no special relationships that correlated with either the virulence of these strains for man or their geographical distribution. All the variola DNAs were clearly very different from those of vaccinia and monkeypox viruses. By comparing gels of DNA fragments from several isolates of variola virus, K. R. Dumbell (personal communication, 1984) showed that DNAs from 4 alastrim strains were

### Variation in the Virulence of Poxviruses

It is notoriously difficult to develop laboratory tests to determine the virulence of viruses. The best that can be done is to test the lethality of virus strains in laboratory animals of the same species as those in which the disease is spreading naturally. For variola virus, virulence tests in man were clearly impossible, and they were not practicable in primates. Sarkar tested many strains of variola major virus from Calcutta in chick embryos and baby mice and produced some evidence of differences in virulence for these hosts that appeared to be correlated with virulence for man, but other virologists were unable to reproduce these results, although few attempted to do so. Further, the fact that the highly lethal haemorrhagic-type smallpox usually produced discrete ordinary-type smallpox in case contacts led most epidemiologists to question the relevance of these results. Certain laboratory tests were successfully used for distinguishing one strain of variola virus of low virulence (alastrim virus) from variola major virus, but failed to distinguish between the equally mild African variola minor virus and variola major virus (Dumbell & Huq, 1986).

The variations in virulence that might be expected in a poxvirus that has been spreading naturally for some years can be assessed in animal models. Myxomatosis in the rabbit, *Oryctolagus cuniculus*, provides a good example, in which the lethality and survival times in groups of rabbits were used as the test for virulence of the virus (Fenner & Ratcliffe, 1965; Fenner, 1983). Two different strains of myxoma virus (a member of the genus *Leporipoxvirus*) were used to initiate the disease among wild rabbits in Australia and Europe, and it became enzootic in both continents. Initially both introductions caused very high mortalities (over 99% case-fatality rates), but within a few years tests of the virus in genetically unselected laboratory rabbits showed that a wide range of strains of different virulence had evolved, although no strain has yet been recovered from naturally infected rabbits that is as attenuated as some strains derived by laboratory manipulation. This example shows that with a virus that was initially extremely virulent, several different strains which differed substantially in virulence arose within a few years and persisted in nature. This development occurred within a decade; it seems highly likely that a similar range of strains of variola virus of different virulence for man occurred in countries in which smallpox had been endemic for centuries.

Fig. 2.9. Dendrogram illustrating the similarities and differences between *Hind*III cleavage sites on 6 variola DNAs, compared with 4 monkeypox and 2 vaccinia DNAs (see legend of Fig. 2.7). Number of attributes = 36. Origin of DNAs as indicated; V. maj. = variola major; V. min. = variola minor; Mpox = monkeypox. Full details of the origins of the viral strains are given in Esposito & Knight (1985), from which the data on restriction sites were derived.

similar but differed from the DNA of the classical variola major strain, Harvey, whereas the DNAs of all the variola minor isolates from Africa (Botswana, Ethiopia and Somalia) resembled that of Harvey, rather than those of alastrim virus.

Digestion with *SaI*I showed that the two Netherlands "whitepox" virus isolates (see Chapter 30) were identical with a strain of variola virus from Vellore, India, that had been handled in the laboratory at the time of their recovery—a pattern that was unique among 21 strains of variola virus examined (Dumbell & Kapsenberg, 1982).

Most of the data on DNA mapping illustrated in this chapter involve the use of the restriction endonuclease *Hind*III. Comparison of single strains of variola, vaccinia and monkeypox viruses using 5 other restriction endonucleases (*Ba*I, *Sma*I, *Kpn*I, *Sa*I and *Xho*I) confirmed the conclusions about their relationships derived from analyses with *Hind*III (Esposito & Knight, 1985).

### Differences between the DNAs of Variola and Monkeypox Viruses

Because variola virus and monkeypox virus both cause a severe generalized poxvirus infection of man, special attention has been devoted to comparing their DNAs. Dumbell and his colleagues have used two techniques: fine structure mapping of equivalent *Hind*III fragments and analysis of heteroduplex formation, as revealed by electron microscopy.

Using the first method, Dumbell & Dollery (personal communication, 1984) have examined 7 corresponding cloned *Hind*III fragments of variola and monkeypox viruses, all derived from the central conserved position of the genome, with 20 restriction endonucleases. Their results are summarized in Table 2.5. There were between 2 and 6

(average 3.4) cleavage sites per kilobase pair (kbp), and the percentage of sites not shared varied, for different fragments, between 20% and 50% (average 30%).

Using similar cloned fragments of these two viruses, Kinchington et al. (1984) compared the threshold denaturation by formamide of homoduplexes and heteroduplexes. This method is sensitive and revealed a region of significant heterogeneity occurring in 4–6 kbp out of 43–45 kbp of the conserved region. The method has considerable potential and important conclusions can be expected to emerge from its further exploitation.

### Genetic Studies

Because in recent years variola virus could be handled only in microbiologically highly secure laboratories, very few genetic studies have been carried out with it. However, as would be expected from the generality of recombination throughout the *Orthopoxvirus* genus (Woodroffe & Fenner, 1960), mixed infection of cells with variola virus and another orthopoxvirus was found to yield some hybrid progeny. Such progeny were obtained from mixed infections with rabbitpox and alastrim viruses (Bedson & Dumbell, 1964a) and cowpox and variola major viruses (Dumbell & Bedson, 1964; Bedson & Dumbell, 1964b). It was hoped that study of the latter might provide information on the origin of vaccinia virus.

By using the phenomenon of non-genetic reactivation (see above) and incubating inoculated eggs above the ceiling temperature of the active virus (variola minor or variola major viruses) many hybrid clones were obtained. These clones appeared to be stable in their biological characteristics; they showed a wide variety of combinations of properties, some being like those of one or other of the

<sup>a</sup> Based on Bedson & Dumbell (1964b).<sup>b</sup> R = red, W = white, I = intermediate; U = ulcerated, O = non-ulcerated.<sup>c</sup> Presence of "d" antigen (Rondle & Dumbell, 1982).<sup>d</sup> Sensitivity of viral thymidine kinase to feedback inhibition by thymidine triphosphate (Bedson, 1982).<sup>e</sup> +++ = large papule with haemorrhage and necrosis; + = small pink papule; 0 = insignificant lesion.

parental species, others being intermediate (Table 2.6).

Each of the 7 markers examined by Bedson & Dumbell (1964b), as well as sensitivity of the viral thymidine kinase to inhibition by thymidine triphosphate, studied later by Bedson (1982), and the presence of the "d" antigen (Rondle & Dumbell, 1982), was capable of segregating independently. The authors suggested that if enough hybrids were tested it would be possible to obtain one that resembled vaccinia virus in all these biological properties. However, it is unlikely that the restriction map of the DNA of such a virus would resemble that of vaccinia virus.

### Species Diagnosis

The most useful biological characteristics for species diagnosis of variola virus are the production of small dense white pocks (0.3–0.6 mm in diameter) on the CA membrane, with a low ceiling temperature (37.5 °C for alastrim virus and 38.5 °C for all other strains), the low virulence for mice and chick embryos, the failure to grow in rabbit skin and the capacity to produce a cytopathic effect in pig embryo kidney cells and hyperplastic foci in HeLa cells. When these characteristics were found in material obtained from a case of suspected smallpox they constituted positive confirmation of the diagnosis; indeed, the recovery of typical variola virus pocks on the CA membrane was usually accepted as diagnostic.

It is worth noting, however, that combinations of properties rather like this are found with both camelpox virus and taterapox virus (Table 2.3). The source of the material usually removes any uncertainty; neither camelpox virus nor taterapox virus has ever been found to produce disease in man and variola virus has never been recovered from animals under conditions in which no suspicions arose of laboratory contamination (see Chapter 30). The 3 viruses can also be differentiated by laboratory tests:

(1) Only variola virus produces dense white pocks at all temperatures of incubation at which pocks develop.

(2) Variola virus produces hyperplastic foci and camelpox virus produces giant cells in several human and primate cell lines (Baxby, 1974).

(3) Taterapox virus is serially transmissible in rabbit skin (Gispen, 1972); variola virus is not.

(4) Taterapox virus is cytotoxic for RK 13 cells, in which variola virus produces hyperplastic foci (Huq, 1972).

(5) Only variola virus produces a generalized disease in primates.

A definitive diagnosis of variola virus can be made by restriction endonuclease digestion of the viral DNA (see Fig. 2.6 and 2.9).

### VACCINIA VIRUS

The vast bulk of experimental work on *Orthopoxvirus* as a genus and *Poxviridae* as a

family has been carried out on one species—vaccinia virus (see Holowczak, 1982; Fenner et al., 1987). It has also been used as a live virus vaccine more extensively, and for a much longer period, than any other immunizing agent.

### Isolation from Natural Sources

The problem of the origin or origins of vaccinia virus is considered in Chapter 7. Here it is relevant to mention that the virus has been isolated from skin lesions of several species of domestic animals (Table 2.7). During periods when vaccination of humans against smallpox was being vigorously pursued there were clearly numerous opportunities for infection to be transferred from recently vaccinated persons to various domestic animals, with subsequent spread in herds either by milkers acting as vectors or by some other route.

Some cases of "cowpox" in cattle (Dekking, 1964; Dahaby et al., 1966; Maltseva et al., 1966; Topciu et al., 1976) and of "camelpox" in camels (Krupenko, 1972) have been caused by vaccinia virus. It is likely that all cases of buffalopox (Lal & Singh, 1977), in both Egypt and India, were caused by vaccinia virus. Although one strain of "buffalopox" virus had a ceiling temperature of 38.5 °C (Baxby & Hill, 1971), it had the DNA map of vaccinia virus (K.R. Dumbell, personal communication, 1983). As recently as 1986, buffalopox has been reported from several areas in central India. Four isolates recovered from infected buffaloes were shown by *Hind*III electropherograms to be strains of vaccinia virus (K. R. Dumbell, personal communication, 1986).

Rabbitpox virus warrants particular mention, since it has been extensively used in

studies of pathogenesis and orthopoxvirus genetics, including the construction of the first DNA map of vaccinia virus. The name was first given to a strain of vaccinia virus that caused severe epidemics in laboratory rabbit colonies in New York in 1933–1934 (Greene, 1933; Rosahn & Hu, 1935). Subsequently, a similar virus of high virulence for rabbits was recovered from a colony of rabbits in Utrecht, Netherlands, under conditions which were said to preclude the infection of the animals with vaccinia virus (Jansen, 1946). Both would be classified as "neuro-vaccinia", in that they are highly virulent by intracerebral injection in rabbits and produce ulcerated haemorrhagic pocks on the CA membrane.

Two viruses recovered in unusual circumstances in central and western Africa, termed "MK-10-73" and "Lenny" respectively, were proved by DNA mapping to be strains of vaccinia virus with a lower ceiling temperature (39.5 °C and 38.5 °C respectively) than standard strains (41 °C) (K.R. Dumbell, personal communication, 1984). MK-10-73, said to have been isolated from the kidney of a wild monkey captured in Zaire, was processed in Moscow (Shelukhina et al., 1975). "Lenny" was recovered from a severely malnourished Nigerian woman who died after an illness with fever and a generalized rash that was very like eczema vaccinatum (Bourke & Dumbell, 1972). The origin of these strains is obscure. Temperature-sensitive (*ts*) mutants of vaccinia virus are readily obtainable in the laboratory (Chernos et al., 1978; Dales et al., 1978; Sambrook et al., 1966). Contamination at some stage cannot be excluded with MK-10-73. "Lenny" resembles the Wyeth strain of vaccinia virus, then being used for vaccination in Nigeria, in all biological properties except the ceiling temperature (K.R. Dumbell, personal communication, 1984); presumably it was a naturally occurring *ts* mutant, perhaps selected by the unusual conditions under which it grew (it was obtained 16 days after the rash appeared).

Rabbit (rabbitpox)	Jansen (1946); Rosahn & Hu (1935)

<sup>a</sup> Possibly a contaminant, from the field (Zaire) or in the laboratory.

### The Variability of Strains and their Pathogenicity

In sharp contrast to variola virus, which has a narrow host range, vaccinia virus has a very wide host range and grows rapidly and to high titre in many species of animals and in most kinds of cultured cells. In chick embryos,

it produces large pocks on the CA membrane within 48 hours, whereas other orthopoxviruses produce smaller pocks and take 3 days to reach the optimum size for pock counts.

#### *Neurovaccinia and dermal vaccinia*

Two terms occur in older works on vaccinia virus that need some explanation: "dermal vaccinia" and "neurovaccinia". Early workers usually maintained vaccinia virus by passage through calves, sheep or rabbits, the animals usually being inoculated by scarification (see van Rooyen & Rhodes, 1948). When the skin lesions reached a sufficient size the infected skin area was scraped, the material thus obtained being called "dermal vaccinia" or "dermovaccine". Strains of vaccinia virus that were maintained by intracerebral inoculation of rabbits, sometimes with occasional testicular passage (Levaditi et al., 1922, 1938), were called "neurovaccinia".

#### *Differences between strains of vaccinia virus*

Two systematic studies have been made of the biological characteristics of various laboratory strains of vaccinia virus (Fenner, 1958; Ghendon & Chernos, 1964). A variety of differences were found, involving the production of haemagglutinin, heat resistance of the virion, pathogenicity in rabbits and mice (Fenner, 1958; Table 2.8), and plaque morphology and virulence for monkeys (Ghendon & Chernos, 1964). The traditional division of strains into "dermovaccine" and "neurovaccine" broadly differentiated viruses of lower and higher virulence for the laboratory animals used; in particular, the occurrence of haemorrhagic pocks on the CA membrane was correlated with the produc-

tion of large indurated skin lesions with a purple centre following the intradermal inoculation of rabbits. White pock mutants of the "neurovaccine" strains produced small pink nodules in the rabbit skin.

Some strains or mutants of vaccinia virus fail to produce haemagglutinin. Rabbitpox virus (Utrecht strain) is one example (Fenner, 1958). Another HA<sup>-</sup> mutant (IHD-W) produces a non-glycosylated form of the 89 000 molecular weight polypeptide, the glycosylated form of which Payne (1979) identified as the haemagglutinin. As with rabbitpox virus, infection with the mutant did not evoke the production of haemagglutinin-inhibiting antibodies, suggesting that glycosylation must produce an important conformational change in the secondary structure of the polypeptide.

#### *Differences in DNAs of different strains of vaccinia virus*

In spite of this variability in biological characteristics, all strains of vaccinia virus that have been examined have remarkably similar DNAs, as judged by restriction endonuclease analysis. Fig. 2.10 illustrates the similarity between the DNAs of 5 strains of vaccinia virus and their difference from variola and monkeypox DNAs, using three restriction endonucleases. The vaccinia strains compared included a classical "neurovaccinia" strain (rabbitpox Utrecht) and two classical dermal strains (LS and HI).

#### **Variation within a Strain**

Several investigators have shown that uncloned stocks of most orthopoxviruses are in

Table 2.8. Some biological characteristics of several different laboratory strains of vaccinia virus<sup>a</sup>

<sup>b</sup> R = red; W = white; U = ulcerated; O = non-ulcerated.

<sup>c</sup> +++ = large papule with haemorrhage and necrosis; + = small papule; 0 = insignificant lesion.

fact mixtures of genetically dissimilar virions. For example, since orthopoxviruses which produce haemorrhagic pox yield, on cloning, a substantial proportion of white non-ulcerated pox (varying between 0.01% and 1%, according to species; Gemmell & Fenner, 1960; Dumbell & Archard, 1980), stock preparations of those viruses must contain several different white pox mutants.

Using other methods of assay, stocks of vaccinia virus which appear to be homogeneous with respect to the type of pox produced can sometimes be shown to be mixed, either in the plaques produced on selected kinds of cells (Ghendon & Chernos, 1964) or by heterogeneity in the patterns produced on analysis with restriction enzymes (Wittek et al., 1978).

### Genetic Studies

Genetic recombination occurs when single cells are co-infected with two strains of virus with several different marker properties. Early experiments on recombination (Fenner, 1959) utilized a "dermal" and a neurovaccinia strain (rabbitpox). Subsequently, the observation that all vaccinia strains producing ulcerated haemorrhagic pox on the CA membrane yielded white pox mutants (Fenner, 1958) led to the demonstration of recombination between some of these mutants but not others (Gemmell & Fenner, 1960). Certain white pox mutants were shown to be host-cell-restricted conditional lethal mutants (Fenner & Sambrook, 1966). Unlike the wild-type virus and some of the white pox

mutants, they failed to replicate in pig kidney cells. Subsequent studies (Lake & Cooper, 1980) showed that the pig-kidney-cell-restricted mutants had deletions at the left-hand terminus and the white pox mutants that grew in pig kidney cells had deletions at the right-hand terminus of the rabbitpox virus genome. Although segments of DNA were lost in the terminal deletions, the changes were not always simple deletions; terminal sequence duplication and transposition were also involved (Moyer et al., 1980).

Suites of temperature-sensitive conditional lethal mutants of rabbitpox and vaccinia viruses have also been assembled (Sambrook et al., 1966; Padgett & Tomkins, 1968; Chernos et al., 1978) and have been employed in experiments on the biogenesis of vaccinia virus (Dales et al., 1978).

A new era in poxvirus genetics began when fragments of vaccinia virus DNA obtained after digestion with restriction endonucleases were cloned in *Escherichia coli* (Wittek et al., 1980). The whole genomes of several strains of cowpox, vaccinia and variola viruses have now been cloned, and detailed analysis of the structure and function of poxvirus DNA has begun. In other experiments based on cloned viral DNA, fragments of foreign DNA have been incorporated into the vaccinia virus genome and expressed during infection (Smith et al., 1983). This opens up the possibility that after suitable genetic manipulation vaccinia virus may be used for the vaccination of humans or domestic animals against diseases caused by a variety of infectious agents other than orthopoxviruses (Quinnan, 1985).

Fig. 2.10. Dendrogram illustrating the similarities and differences between *Hind*III, *Sma*I, and *Xho*I cleavage sites on DNAs from 5 vaccinia strains originating in different countries, compared with 2 monkeypox and 2 variola DNAs (see legend of Fig. 2.7). Number of attributes = 66. Full details of the origins of the viral strains are given in Esposito & Knight (1985), from which the data on restriction sites were derived.

### Species Diagnosis

As illustrated in Fig. 2.7 and in more detail by Mackett & Archard (1979), the genome of vaccinia virus is distinctive, and comparison of DNA maps provides conclusive evidence whether any isolate under examination belongs to this species. Biological characteristics that are particularly useful for diagnostic purposes are the rapid growth of large pocks on the CA membrane, which may vary from haemorrhagic to dense white in appearance, the high ceiling temperature of growth on the CA membrane (41 °C or higher) and the broad host range.

### COWPOX VIRUS

Cowpox virus is of interest in the context of smallpox eradication because of its historic involvement in the discovery of vaccination (see Chapter 6) and because it is transmissible to man (see Chapter 29). Research over the last decade has shown that there is a large number of somewhat similar viruses which can cause infections in a variety of animals, rodents probably being the reservoir hosts (see Chapter 29). In this book all these viruses are included within the cowpox virus species.

#### Cowpox and Horsepox in Europe

The occurrence of a sporadic pox disease of cows transmissible to man had been known for centuries and was brought to public attention by the observations of Jenner. The distinctive character of the usual cause of cowpox—the *Orthopoxvirus* species now categorized as “cowpox virus”—was first recognized by Downie (1939a,b). Other causes of what is called “cowpox” are vaccinia virus, usually derived from a human source, and a species of *Parapoxvirus* that causes milker’s nodules in man. The last-named virus was one of the causes of Jenner’s “spurious cowpox”. It is only the first of these 3 viruses with which we are concerned here.

“Horsepox” is a tantalizing disease for a modern virologist who is interested in the history of Jenner’s vaccine. Jenner confused the situation by suggesting that cowpox in cows usually originated from “grease” of horses—a lesion of the fetlocks (Plate 2.15A) that may be caused by several different agents, most commonly the bacterium *Dermatophilus*

*congolensis* (Gillespie & Timoney, 1981). During the 19th century, a poxvirus (“horsepox virus”) was an occasional cause of this syndrome. Loy (1801) demonstrated that material from such a lesion produced cowpox when inoculated in cows’ teats, and he protected a child from challenge variolation by “equination”. Usually, according to Crookshank (1889), horsepox was associated with pustular lesions on the perineum or the head of the horse (Plate 2.15B), as well as sometimes on the fetlocks (grease). Both Chaveau (cited by Crookshank, 1889) and Fleming (1880) believed that horsepox was due to the accidental infection of horses with cowpox virus. Evidence now available suggests that both cowpox and in the past at least some cases of horsepox were due to the incidental infection of these animals by cowpox virus, which probably circulates in rodents; or, as Jenner suggested, it may have been transferred accidentally from horses to cows, or vice versa, by man. More recently horsepox, like “cowpox”, has been produced by the infection of horses with vaccinia virus originating from vaccinated human subjects (Kii & Ando, 1937). Finally, Baxby (1981) has suggested that horsepox, which he postulates was a disease distinct from the infection of horses with cowpox virus, and which became extinct at about the end of the 19th century, was in fact caused by vaccinia virus.

#### Genetic Studies

White pock mutants, which have been important for genetic studies of orthopoxviruses and in speculations about the evolution of both vaccinia and variola viruses, were first recognized in experiments with cowpox virus inoculated on the CA membrane (Downie & Haddock, 1952; Tongeren, 1952). Early attempts to exploit this system for genetic studies of cowpox virus were frustrated by the failure to obtain recombination between many combinations of separately isolated mutants derived from the Brighton strain of cowpox virus (Dumbell, unpublished results, 1960; Greenland & Fenner, unpublished results, 1960). This failure was explained by the discovery that all white pock mutants of the Brighton strain involved substantial deletions from the right-hand end of the genome (Archard & Mackett, 1979).

Amano et al. (1979) found that all white pock mutants of cowpox virus failed to

M. SOEKAWA

**Plate 2.15.** **A:** Grease, a lesion of the fetlocks caused by a variety of agents. **B:** Horsepox. Illustration of a case investigated by Professor Peuch of Toulouse, which occurred during an outbreak of horsepox in Toulouse in 1880. (B from Crookshank, 1889.)

produce an early cell-surface antigen that was produced in infected cells by all the parental strains (10 wild-type and 28 white pock mutants were investigated). Randle & Dumbell (1962) showed that another antigen, "d", which was present in extracts of cells infected with wild-type cowpox virus did not occur in its white pock mutants. Subsequently, Randle & Dumbell (1982) demonstrated that "d" antigen occurred in several orthopoxviruses that produced necrotic haemorrhagic lesions after intradermal inoculation in rabbits (cowpox virus, neurovaccinia strains including rabbitpox virus, and certain recombinants between cowpox and variola viruses), but not in those that did not produce such lesions (cowpox white mutants, variola and some recombinants between variola and cowpox viruses—see Table 2.6).

### Species Diagnosis

The most reliable biological indicators of cowpox virus are the production of large haemorrhagic pocks on the CA membrane, with a ceiling temperature of 39 °C, the production of a large haemorrhagic lesion after intradermal inoculation in rabbits, the

wide host range, and the production of A-type as well as B-type inclusion bodies in infected cells. Although there is greater variability between the DNA maps of different strains of cowpox virus (using the broad definition adopted here) than is the case with other species of *Orthopoxvirus* (see Chapter 29; Fig. 29.4), all strains of cowpox virus cluster together in the dendrogram and can be readily differentiated from other orthopoxviruses.

### LABORATORY CONFIRMATION OF SMALLPOX DIAGNOSIS

Laboratory methods played a crucial role in the global smallpox eradication campaign; indeed the achievement of eradication could not have been confidently certified without their use. The development of laboratory support for the Intensified Smallpox Eradication Programme is outlined in Chapter 10. The laboratory also provided support for the clinical diagnosis of smallpox. This was not of much importance in endemic countries when smallpox was a common disease, but was of great value in non-endemic countries confronted with suspected imported cases (Mac-

rae, 1982) and in the endemic countries as eradication approached (Ježek et al., 1978f).

### Preparation of a Guide for Laboratory Diagnosis

In October 1967 a WHO Scientific Group on Smallpox Eradication met in Geneva. Among other recommendations, it proposed that laboratories for diagnosis should be developed in each of the larger countries and regional laboratories should be designated to serve groups of smaller countries (WHO Scientific Group on Smallpox Eradication, 1968). In April 1968 a group of experts met in Philadelphia, USA, to commence the preparation of a manual, *Guide to the Laboratory Diagnosis of Smallpox for Smallpox Eradication Programmes*, which was intended to provide information on procedures that could be performed in the surveillance activities of smallpox eradication programmes in endemic areas.

The guide, which incorporated the comments of a number of other experts, was published in 1969 (World Health Organization, 1969a). It described methods of specimen collection, microscopic examination of smears (by the method of Gispén, 1952), precipitation in gel, isolation of virus on the CA membrane, the maintenance of records and the layout of a smallpox diagnostic laboratory (see Chapter 30, Fig. 30.3A). In retrospect, the value of the guide can be assessed by a review of the changes that occurred as the eradication programme proceeded.

(1) Examination of stained smears was not widely practised, and in developed countries this method was completely displaced by electron microscopic examination of negatively stained preparations.

(2) The guide facilitated the development of national diagnostic laboratories in some heavily populated countries, such as India and Bangladesh. As eradication approached in these countries, duplicate specimens were sent to the WHO collaborating centres (see Chapters 15 and 16).

(3) The concept of a regional laboratory network did not materialize; instead reliance was placed on the services of the WHO collaborating centres in Moscow, USSR, and Atlanta, USA.

(4) A special kit was later developed for the collection and dispatch of specimens (see Chapter 10, Plate 10.6).

### Methods of Laboratory Diagnosis

Laboratory diagnostic methods used can be divided into three groups: those involving the recognition of virions or of viral antigens in material collected from the patient, and inoculation of the virus in laboratory animals (including the CA membrane) or cultured cells. Subclinical infection with variola virus or the retrospective diagnosis of human monkeypox could be recognized only by serological tests (see Chapters 1, 3 and 29). Detailed descriptions of techniques are given by Downie & Kempe (1969) and Nakano (1979, 1982).

#### *Methods involving the recognition of virions*

*Staining for light microscopy.* In smallpox, virions occurred in vast numbers in the vesicle fluid and in pustules and scabs, and pathologists developed a variety of staining methods which made it possible to see the virions in stained smears. Paschen's method (Paschen, 1906), using basic fuchsin, which stained the virions deep red, was probably the most widely used (see Plate 2.1); it was subsequently replaced by silver impregnation techniques (Morosow, 1926; Gispén, 1952). Gispén's method was advocated in the aforementioned WHO *Guide to the Laboratory Diagnosis of Smallpox for Smallpox Eradication Programmes* (World Health Organization, 1969a) as the method of choice for the presumptive diagnosis of smallpox. In skilled hands it was a useful test but was open to misinterpretation by those not familiar with the technique—especially after the lesions became pustular—and it was not widely used.

*Electron microscopy.* Nagler & Rake (1948) were the first to employ electron microscopy for the diagnosis of smallpox, using shadow-cast preparations of crusts or vesicle fluid that had previously been purified and concentrated by centrifugation. However, widespread use of electron microscopy as a diagnostic method was not feasible until the negative staining technique was introduced by Brenner & Horne in 1959. Peters et al. (1962) and subsequently Cruickshank et al. (1966) showed the value of this method for recognizing poxvirus or herpesvirus particles in vesicle fluid and scabs taken directly from patients. Like the examination of stained smears, electron microscopy could not be used to distinguish between variola, vaccinia and monkeypox viruses, which are morphologi-

**Plate 2.16.** Virions of variola virus (A and B) and varicella virus (C) as seen in negatively stained preparations submitted for diagnosis to the WHO Collaborating Centre at the Centers for Disease Control, Atlanta, GA, USA. Bar = 100 nm.

cally indistinguishable, but it was of great value in confirming or possibly excluding poxvirus infection and in distinguishing between poxvirus infection and chickenpox. In 1971 it became an integral part of the diagnostic procedures used by the WHO collaborating centres in Atlanta, USA, and Moscow, USSR. Plate 2.16 shows typical virions of variola virus along with those of herpesvirus (from a patient with chickenpox), as seen in negatively stained specimens of crusts, scrapings or vesicle fluid.

#### *Methods involving the recognition of viral antigens*

Initially, complement-fixation and flocculation tests were used for the demonstration of orthopoxvirus antigens in vesicle or pustule fluid, the former test being considered preferable (Craigie & Wishart, 1936; Downie, 1946). Subsequently, gel precipitation was developed, and an adaptation of this method on microscope slides was described in detail in the WHO guide. This technique was extensively employed in some national campaigns (e.g., in India; Ježek et al., 1978f) in laboratories that did not have an electron microscope available for rapid diagnosis. With adequate amounts of recently collected antigen it was a quick and accurate test (Rao et al., 1970; A.W. Downie, personal communication, 1981).

Other serological tests for viral antigen were sometimes used but never became widely popular. Kitamura et al. (1977a) suggested that direct immunofluorescence could be used for rapid diagnosis in the field, but they and other workers (Tarantola et al., 1981) recorded a number of false positive results, a major disadvantage as the achievement of eradication approached.

#### *Tests in animals and isolation of the virus*

All the methods described so far had the limitation that, if positive, they did not distinguish between different orthopoxviruses. This drawback was of little significance when smallpox was a common disease, but it became increasingly important as eradication proceeded, particularly after human monkeypox was recognized in 1970.

In the early days of virology the only animal diagnostic procedure useful in distinguishing variola virus from varicella virus was the inoculation of monkeys, clearly a method that could not be widely used. Paul's test, which involved the scarification of the rabbit cornea, provided a more widely applicable method, but according to Downie (1946) and Marennikova et al. (1961), it often gave false negative results. However, variola virus produced very characteristic pocks on the CA membrane, which provided a simple and reliable laboratory method for isolating and recognizing that virus.

*Production of pocks on the CA membrane.* It had been known since the 1930s that orthopoxviruses grew on the CA membrane of developing chick embryos, and that when dilute suspensions were used different strains of vaccinia virus produced characteristic pocks. Although others had cultivated variola virus on the CA membrane, Downie & Dumbell (1947b) were the first to demonstrate the reproducible and clear-cut differences between the pocks produced by variola virus and those due to vaccinia virus. CA membrane inoculation soon became the method of choice for the isolation of variola virus (World Health Organization, 1969a). The pocks produced by variola virus are quite

distinctive and can be readily distinguished from those produced by the other orthopoxviruses that are pathogenic for man—vaccinia, cowpox and monkeypox viruses (see Plate 2.5). It has remained the method of choice for the preliminary identification of orthopoxviruses, and it was the fact that the pock morphology of monkeypox virus was different from that of variola virus that led Marennikova et al. (1972a) to make the first laboratory diagnosis of human monkeypox.

**Isolation in cultured cells.** Most human and non-human primate cells, and some cells derived from other species (rabbit kidney and pig embryo kidney cells), are susceptible to infection with variola virus. In most cell systems variola virus causes cell fusion and multinucleated foci; the small (1–3 mm in diameter) hyperplastic foci are quite distinctive when compared with the large (2–6 mm in diameter) plaques produced by vaccinia, monkeypox and cowpox viruses (Kitamura, 1968; see Plate 2.13). Pig embryo kidney cells are unusual in that variola virus, which has a narrow host range, produces a cytopathic effect, whereas most strains of monkeypox virus, which has a wide host range, do not (Marennikova et al., 1971).

Although cell culture was sometimes more

sensitive (Nakano, 1979), inoculation on the CA membrane was generally a more useful test with field material, since positive results could be obtained even with scabs that were contaminated with bacteria (Sarkar & Mitra, 1963), which usually destroyed cell cultures. Also, if the content of viable virus was low it often took several days, and perhaps serial passage, before characteristic lesions occurred in cultured cells, whereas a result could always be obtained within 3 days by CA membrane inoculation.

**Differentiation between orthopoxviruses.** Four species of *Orthopoxvirus* can produce lesions in man: variola, monkeypox, vaccinia and cowpox (see Chapter 29). Each produces distinctive pocks on the CA membrane; in addition, the 4 species can be differentiated by several other biological properties (Table 2.9) as well as by restriction endonuclease mapping of their DNAs.

### Comparison of Different Laboratory Diagnostic Methods

Noble et al. (1970) assessed the value of various laboratory procedures for the diagnosis of variola minor in Brazil. They always

Characteristic	Virus			
	Variola	Vaccinia	Monkeypox	Cowpox
Pock on CA membrane	Small opaque white	Strains vary; large opaque white or ulcerated	Small ulcerated at 35 °C	Large, bright red, haemorrhagic
Ceiling temperature	37.5–38.5 °C	41 °C	39 °C	40 °C
Skin lesion after intradermal inoculation of rabbit	Nil or small nodule, non-transmissible	Strains vary; indurated, sometimes haemorrhagic nodule	Large, indurated haemorrhagic nodule	Large, indurated haemorrhagic nodule
Growth in pig embryo kidney cells	+	+	–	+

<sup>a</sup> Unequivocal diagnosis of all these species can be made by the examination of electropherograms produced after restriction endonuclease digestion of viral DNAs.

obtained positive results with both scabs and vesicular or pustular fluid stored in capillary tubes and tested by electron microscopy and cultivation on the CA membrane; a few such specimens were negative by gel precipitation. They were less successful with material that had been stored as smears on glass slides for up to 2 months at room temperature. In searches with the electron microscope for a maximum period of 10 minutes for each specimen, only 30 out of 52 (58%) were positive. Some of these showed structural degeneration of the virus particles; presumably this had proceeded so far on those diagnosed as negative that no intact virions could be found during the 10-minute search. Twenty-seven out of the 30 specimens found positive by electron microscopy yielded virus when inoculated on the CA membrane; 1 specimen found negative by electron microscopy was positive on CA membrane inoculation. Positive culture was never obtained by serial passage of membranes that appeared normal; occasionally

membranes that had cloudy or non-diagnostic opacities on first inoculation showed unequivocal variola virus pocks on the second passage. Only 41% of the stored smears were positive by gel diffusion.

The most comprehensive analysis of the laboratory diagnosis of smallpox was reported by Nakano (1973), who kindly updated the figures in 1982 to show the situation at that time (Table 2.10). The material under study had been shipped to the Centers for Disease Control, Atlanta, USA, from Africa, South America and Asia and had usually been in transit for between 2 and 4 weeks, and occasionally longer, often at high ambient temperatures. Four methods were used: electron microscopy, gel precipitation, and cultivation on the CA membrane and in Vero cells. By March 1981 a total of 6919 specimens had been examined, many of them from suspected chickenpox cases during precertification testing in Ethiopia and Somalia. Of the 981 positive specimens, 940 were identified as

Table 2.10. Relative efficiency of 4 laboratory methods for diagnosing variola or human monkeypox infections. Tests on material from vesicles or scabs in 981 positive specimens from 6919 cases of suspected smallpox or monkeypox, accumulated between January 1966 and March 1981<sup>a,b</sup>

Method	Specimens positive for poxvirus by any one method or more		Specimens positive for poxvirus by

variola virus and 41 as human monkeypox virus.

Electron microscopy had the advantage of being much the most rapid method of making a presumptive diagnosis, which was a very important requirement, especially in non-endemic countries. In scabs or material that had been some time in transit, it was also the most sensitive, although fields might have to be searched for as long as 30 minutes before a specimen was declared negative. The longer period of search undoubtedly accounted for the greater percentage of successes recorded by Nakano with stored specimens, compared with the experience of Noble et al. (1970). Inoculation on the CA membrane had the great advantage of allowing differentiation between the 4 orthopoxviruses that can infect man (variola, monkeypox, cowpox and vaccinia viruses). It was also the most sensitive with fresh specimens of vesicular fluid, since one infectious particle was potentially capable of producing a pock. Positive results were obtained on the CA membrane with 14 specimens that were negative by electron microscopy, whereas 97 specimens were positive by electron microscopy but negative by CA membrane inoculation. However, Nakano (1979) found that the susceptibility of the CA membrane, although usually quite satisfactory, was sometimes unacceptably low, as judged by control inoculation in cultured cells. For this reason he found it useful to make inoculations on cultured cells, especially with critical specimens in which recovery of the responsible virus was very desirable (e.g., in suspected human monkeypox). Out of 186 specimens that were tested by all 4 methods, 182 were positive by electron microscopy, 135 by tissue culture inoculation and 117 by CA membrane inoculation—i.e., 18 specimens were positive by tissue culture but negative on the CA membrane. Growth in pig embryo kidney cells was sometimes used to differentiate between variola and monkeypox viruses. Nakano confirmed the finding of Noble et al. (1970) that gel precipitation was the least sensitive technique and that it was often negative in lesion material that had been exposed to ambient temperatures for several days.

#### Tests for Species-Specific Viral Antibodies

Most serological tests for orthopoxvirus antibodies were positive in the late stages of

smallpox, except in some cases of haemorrhagic-type smallpox, which were in any case fatal, but the detection of antibodies was irrelevant for the ordinary laboratory diagnosis of smallpox. However, serological tests were useful in determining whether certain patients who had recovered from a febrile illness associated with a rash had suffered from smallpox. They provided the only way of diagnosing variola sine eruptione and sub-clinical infections, the complement-fixation test being particularly valuable because of the short period after infection that it remained positive (see Chapter 1).

Serological tests were important in another context—namely, the specific diagnosis of prior infection with monkeypox virus, whether in humans or in animals (see Chapter 29). Several attempts were made to develop methods for differentiating between antibodies due to prior infection with variola, monkeypox and, in certain cases, other orthopoxviruses (see Chapter 3). The methods described depended on the multiple absorption of positive sera and the recognition of antibody to a particular viral species after such absorption. Immunoprecipitation (Gispen & Brand-Saathof, 1974) and immunofluorescence (Gispen et al., 1974) were used to differentiate antibodies due to infection with variola, monkeypox and vaccinia viruses. Subsequently, Hutchinson et al. (1977) and Marennikova et al. (1981) developed absorption tests for detecting specific antibodies using radioimmunoassay and ELISA respectively. All these methods required that adequate amounts of relatively potent serum should be available for testing, and the requisite multiple absorptions were tedious and time-consuming. However, they were useful in providing evidence of past monkeypox virus infection in man and in certain species of monkeys and squirrels.

#### RESISTANCE TO PHYSICAL AND CHEMICAL AGENTS

The infectivity of orthopoxviruses is in general relatively unaffected by environmental conditions, compared with that of many other viruses. The focus of work on the resistance of vaccinia and variola viruses to physical and chemical agents was quite different: with vaccinia virus the practical objectives were either to ensure the viability and potency of stored vaccine preparations or to

produce an effective inactivated vaccine; with variola virus interest was centred on epidemiological parameters such as its viability in droplet nuclei and the persistence of infectivity in scabs and on fomites.

### Vaccinia Virus

The heat resistance of vaccinia virus, prepared in various ways and exposed to different temperatures, was of major importance in the development of efficient vaccination programmes (see Chapter 11). Glycerolated liquid vaccine, while relatively stable at refrigerator temperature for a few weeks, was quickly inactivated at higher temperatures, especially if exposed to sunlight.

Kaplan (1958) studied the inactivation of vaccinia virus at various temperatures ranging from 50 °C to 60 °C. There was an initial rapid fall in infectivity to  $10^{-5}$  or  $10^{-6}$  of the original titre, followed by inactivation of the residual virus at a much slower rate. Perhaps this phenomenon provides an explanation for the successful long-distance transportation of vaccinia virus that took place from time to time during the 19th century (see Chapter 6). The persistent infectivity was not due to the selection of genetically resistant virus, but was shown by Woodroffe (1960) to be attributable to some change that occurred during the storage of concentrated preparations of virus in the liquid state. The infectivity of freshly prepared suspensions of partially purified vaccinia virions suspended in McIlvaine's buffer was completely destroyed within 60 minutes at 55 °C and within 90 minutes at 50 °C.

Camus (1909), working in France, and later Otten (1927) in Batavia (Jakarta) showed that crude vaccine dried slowly *in vacuo* over sulfuric acid, and stored *in vacuo*, was much more stable than liquid vaccine. Such preparations were used in the French colonies in Africa and for the elimination of smallpox in the Netherlands East Indies (Indonesia) in the late 1930s (see Chapter 8). However, the material was difficult to reconstitute, it was often heavily contaminated with bacteria, and there was a good deal of variation between batches. Subsequently, freeze-drying, which had long been used on a laboratory scale for preserving and transporting viruses and bacteria, was developed on a commercial scale for smallpox vaccine (see Chapter 7). Such material was very stable; Kaplan (1969) reported

that an early production batch of freeze-dried vaccine withstood storage at 45 °C for at least 6 years without loss of potency.

Other methods of inactivation of vaccinia virus were relevant mainly in relation to efforts to produce an inactivated virus vaccine (Turner et al., 1970; see Chapters 3 and 7). Most workers found heating to be unsuitable, as it destroyed antigenicity. Other methods of inactivation that were investigated included ultraviolet irradiation, which had the disadvantage that a small overdosage severely damaged antigenicity (Kaplan, 1969), and formaldehyde, which also damaged antigenicity (Amies, 1961). Photodynamic inactivation with methylene blue (Turner & Kaplan, 1968) and gamma irradiation (Marennikova & Macevič, 1975) appeared to inactivate infectivity with little effect on antigenicity.

### Variola Virus

Periodic assays showed that in temperate climates smallpox scabs could retain infectivity at room temperature for several years. Downie & Dumbell (1947a) recovered variola major virus from crusts stored at room temperature, in the dark or in daylight, for up to 1 year; Wolff & Croon (1968) recorded the persistence of viable alastrim virus in scabs kept in envelopes in a laboratory cupboard for over 13 years. The potential significance of these findings in relation to a possible return of smallpox is discussed in Chapter 30; of more immediate concern to the smallpox eradication programme was the degree to which viability might persist in some tropical countries in which variolation was still practised during the 1970s. Huq (1976) investigated the persistence of viable variola major virus in scabs maintained at various temperatures and relative humidities through 16 weeks of the hot season in Bangladesh (late May to mid-July). Her results are summarized in Table 2.11. The initial titre was  $10^{8.3}$  plaque-forming units. Infectivity fell off rapidly at 35 °C, but at 4 °C viable virus was still present after 16 weeks, both at a relative humidity of 60–62% and in a desiccator (relative humidity, <10%). At ambient temperature the relative humidity affected survival, virus persisting in a viable state for 8 weeks at high humidity and for 12 weeks at low humidity. These results confirm the observation of MacCallum & McDonald (1957) that virus viability was adversely affected by both high

temperatures and high relative humidity. Since these conditions prevailed in most of the countries in which endemic smallpox still occurred in the 1970s, prolonged survival of viable virus did not seem to pose a major long-term threat. However, virus could remain viable for long enough for fomites to present at least a short-term problem, especially in temperate climates.

The foregoing discussion relates mainly to the persistence of the viability of variola virus in scabs in relation to the threat that this might have posed to the eradication programme. One advantage of the heat resistance of variola virus was that it made possible the shipment of swabs and scabs from endemic countries to the WHO collaborating centres in Moscow and Atlanta, in which diagnostic

laboratory studies could be carried out. Vesicle fluid or scab material was mailed in special containers, and although such transmission often took 2 weeks or longer, electron microscopy almost always revealed positive results in cases of smallpox, and chick embryo inoculation was often successful.

An epidemiologically important aspect of the resistance of variola virus to environmental conditions, discussed at greater length in Chapter 4, was its viability in droplets and droplet nuclei under various conditions of temperature and humidity. Short-term (60-minute) experiments showed that variola virus was relatively resistant in aerosols, and viability was only slightly less persistent at high relative humidities (Mayhew & Hahon, 1970). In other experiments, using vaccinia virus as a model, Harper (1961) found that over a longer time interval, viability in aerosols was greatest at low temperatures (10.5-11.5 °C) and low relative humidity (<50%). The adverse effect of high relative humidity was greater at higher temperatures (Table 2.12). If, as is likely, this property also applies to variola virus, it has implications in relation to contact infection and the seasonal fluctuations in the incidence of smallpox, which was more common in the colder and drier months of the year (see Chapter 4).

### SPECULATIONS ABOUT THE ORIGINS OF VARIOLA VIRUS

The elucidation of the history of smallpox over the last 2000 years, which is attempted in Chapter 5, involves much speculation, and alternative interpretations are possible for most of the ancient "plagues" that have been accepted by some authorities as outbreaks of

smallpox. Suggestions as to how smallpox arose as a disease of humans are even more a matter of guesswork.

### The Diversity and Specificity of Viruses of Man

There are some 20 well-characterized families of viruses of vertebrates, 18 of which contain one or more viral species that can infect man (White & Fenner, 1986). No less than 13 of these families include species which can be maintained in man as the sole vertebrate host; many of these viruses are specific for man and do not cause natural self-perpetuating infections in other vertebrates. On the other hand, each of these 13 families contains species of viruses that cause natural infections in vertebrates other than man. Among the family Poxviridae, 8 viral species, belonging to 4 different genera, can cause infections of man, but only 2 species—variola virus and molluscum contagiosum virus—are specifically human pathogens. For every specifically human virus the question of origins relates to how long ago, in the course of biological evolution, did the viral species in question exhibit the capacity to be maintained indefinitely by human-to-human (or proto-human-to-protohuman) spread.

### Requirements for Human-to-Human Transmission

#### General principles

Whether or not a virus can be maintained indefinitely by passage from person to person in populations of various sizes depends on: (1) certain characteristics of the virus, notably its capacity to undergo antigenic change; (2) characteristics of the pathogenesis of the infection, especially the quality of the immune response and whether persistent infection or recurrence of infectivity occur; and (3) characteristics of the population biology of the host, notably the rate of accession of new susceptible subjects (Fig. 2.11). Viruses such as the herpesviruses, which exhibit persistent infection and recurrent infectivity, can be maintained in very small populations, even though they provoke a long-lasting immune response and circulate in a population of long-lived animals. However, viruses such as variola virus, which do not undergo antigenic change sufficient to overcome the

Fig. 2.11. Approximate sizes of populations required for maintaining the endemicity of several specifically human viral diseases. (From Black, 1982.)

immunity of previously infected hosts and which do not cause persistent infection with recurrent infectivity, will survive only in populations sufficiently large or with a sufficiently rapid turnover rate to ensure that some susceptible individuals are always likely to be infected. In this connection the turnover rate is affected by mobility and contact between population groups.

#### The case of variola virus

It was possible to eradicate smallpox in the 20th century because it was a disease that could persist only by transmission from one susceptible human being to another. In the absence of an alternative animal host, and lacking the capacity to cause endogenous recurrent disease in an individual who had been infected, the virus could persist in a population only if enough susceptible humans were constantly available to maintain a continuous chain of infection. Studies of the closely analogous situation in measles, both in the cities of the British Isles and the USA

(Bartlett, 1957, 1960) and in the islands of the Pacific (Black, 1966), suggest that a population of not less than 300 000–500 000 is necessary to sustain endemic measles. If, in the case of smallpox we reduce this to perhaps 200 000 because it spread less rapidly than measles, the disease could be sustained indefinitely in man as the sole host only after the introduction of irrigated agriculture—some 10 000 years ago—had initiated the first great population explosion.

What then could have been the source of the virus that caused the disease that has been recognized as smallpox for 2000–3000 years? Two possibilities exist: either man acquired the virus from some animal host in which it could be maintained because the animal occurred in larger numbers and had a much shorter generation time than had man, the hunter-gatherer; or else humans (or perhaps protohumans) had long been the host of an ancestral "variola virus" which produced a different sort of disease, one that could persist in small groups of hunter-gatherers, and subsequently changed its behaviour in the human host. We shall now examine these possibilities.

#### **Possible Derivation of Variola Virus from another *Orthopoxvirus***

Variola virus is usually thought to have been derived from a closely related virus of some other animal, possibly an animal that was domesticated early and thus maintained close relations with early man. There are 4 orthopoxviruses known today that infect animals with which ancient man was or may have been in contact: camelpox, cowpox, ectromelia and monkeypox viruses.

##### *Camelpox virus*

Camelids evolved in the Americas and spread to Asia and North Africa some 3 million years ago. They would certainly have been hunted by early man, but were probably domesticated after sheep and cattle, perhaps some 5000 years ago. As it now occurs, camelpox virus is highly host-specific; its genome map is distinctive and quite different from that of variola virus.

##### *Cowpox virus*

This virus can infect a variety of different species of animal. It is probably maintained in

nature in rodents, but occasionally infects man, cattle, cats and other domestic animals. Its genome is the largest of all the orthopoxviruses but deletion mutations occur commonly, producing progeny with smaller genomes. None of the strains of cowpox virus that have been examined has a genome that looks at all like that of variola virus.

##### *Ectromelia virus*

Now known only as the cause of mousepox in laboratory mice, ectromelia virus has a narrow host range and a distinctive genome map. Its original natural host was probably some field rodent.

##### *Monkeypox virus*

Since human monkeypox is clinically so like smallpox (see Chapter 29), it is natural to think of it as a possible progenitor of smallpox; or perhaps it would be more correct to think of a "proto-monkeypox" virus as having given rise to a "proto-variola" virus. The molecular biology of such a transformation is discussed in Chapter 30; suffice it to say that the DNA of monkeypox virus is no more similar to that of variola virus than is any other known orthopoxvirus DNA (see Fig. 2.7, 2.9 and 2.10).

At the present time monkeypox virus appears to occur naturally only in the tropical rain forests of central and western Africa. There is no evidence that human populations large enough to support the evolution and persistence of a virus with the characteristics of variola virus ever occurred in this part of the world in prehistoric times; 4000–5000 years ago populations of that size appear to have occurred only in the great river valleys of Egypt, the Fertile Crescent, the Indian subcontinent and eastern Asia. A disease recognizable as smallpox was present in Egypt in 1157 BC (if Ramses V did indeed die of smallpox) and in India and China perhaps as long as 2000 years ago. How could monkeypox virus, in its original form or as an evolving variola virus, move from western or central Africa to the Nile valley? The Sahara, as we now know it, would appear to have constituted an impossible barrier. But that was not always the case. Palaeoclimatic studies of Africa are in their infancy, but there is good evidence that the Sahara and the Sahel were much less arid in the period 9000 BC to 2000 BC than they are now, and supported popula-

tions of elephants and giraffes as well as ancient man (McIntosh & McIntosh, 1981). Further south, this savanna-like country merged into tropical rain forests that supported a rich fauna then, as they do now. In this kind of climatic regime, it is not impossible to conceive of the movement of newly evolving variola virus from areas far to the south and west into the Nile valley, where it might have persisted in the large human population of the Middle Kingdom.

### Variola Virus as the Descendant of an *Orthopoxvirus* of Early Man

The other possibility is that variola virus had long existed among protohuman primates and our early ancestors. To explain its persistence in such small populations and the later emergence of smallpox as we know it, it is necessary to invoke the concepts of "K-selection" and "r-selection" (*K* refers to the carrying capacity of the environment; *r* to the maximal intrinsic rate of natural increase) used by ecologists to help to understand physiological and evolutionary adaptations, especially of insects and plants (Pianka, 1970; Southwood et al., 1974).

The human population was in a stage of *K*-selection until irrigated agriculture, which was developed some 10 000 years ago in the river valleys of Asia and northern Africa, vastly increased the potential human food supply and thus initiated the human population explosion that continues to this day—a situation in which *r*-selection became dominant. This change was accompanied by new evolutionary opportunities for viruses. During the phase of *K*-selection of their host, microbial parasites, including viruses, were also subject to *K*-selection. Only agents associated with prolonged or recurrent infectivity—for example, the human herpesviruses—could survive without recourse to an animal host. However, when the population became much larger and the annual input of susceptible individuals increased, viruses which produced diseases that were infectious for a brief period only, and that rendered the host immune thereafter, could survive and evolve. Under such conditions the viruses would be subjected to strong *r*-selection.

It is not difficult to accept this overall concept as being relevant to the evolution of the common respiratory and enteric viruses of man. It could be applied to smallpox in the

following way: Man, the hunter-gatherer, and his forebears were hosts of a specifically human (or protohuman) "proto-variola" virus, which was able to persist in their small populations because infected individuals remained infectious for a long time. When irrigated agriculture allowed man to escape from the restrictions of *K*-selection, new opportunities existed for specifically human viruses, since susceptible populations were then large enough to support viruses that caused diseases which were infectious for a short period and rendered the host immune to reinfection. If a mutant arose from the "proto-variola" virus that multiplied much more prolifically (*r*-selection) and caused an acute generalized infection, it would soon replace its progenitor "proto-variola" virus wherever the human population was large enough. The result might be variola virus and smallpox. This hypothesis would have received strong support if the hypothetical "proto-variola" virus had been found among any of the hunter-gatherer populations in areas in which the population was until recent times subject to *K*-selection—the Americas, Australia and southern Africa. The behaviour of smallpox on first contact with these populations indicates that no such "proto-variola" virus existed there and this hypothesis remains unproved and unlikely.

### Conclusions

We have to conclude that at present we do not know how, when or where variola virus originated. An origin from an orthopoxvirus of some other animal seems probable—and perhaps monkeypox virus may be suggested as the most likely candidate, on the grounds that it causes a disease in humans that is very like smallpox, rather than because of a particularly close resemblance between the DNAs of the respective viruses. Smallpox appears to have occurred for some 3000 years as a disease with the same characteristics as it exhibited up to the time of its eradication in 1977. The ultimate answer to its origin could come from studies of the nature and variability of the genomes of variola virus and other orthopoxviruses. However, with the eradication of smallpox, research on variola DNA is unlikely to be extensively pursued. Even if the problem is in principle soluble, we may never arrive at an answer.

## INTRODUCTION

The term pathogenesis is used to describe the mechanisms involved in the production of disease, including the spread of virus through the body and the physiological responses of the host organism to the infection, of which the most important is the immune response. The pathogenesis of smallpox could be studied in three ways: (1) by using material from human patients, which had the advantage of direct relevance but the disadvantage that planned experiments were not possible; (2) by conducting experiments with variola virus infections of non-human primates; and (3) by conducting experiments with "model" infections—ectromelia (mousepox) in mice, vaccinia (rabbitpox strain) in rabbits, and monkeypox in monkeys. Each of these approaches had advantages and disadvantages. With human subjects, investigation during life was limited to the sampling of body fluids, skin biopsy (rarely), and the examination of postmortem material. No investigations were possible during the incubation period, when most of the critical events in the spread of the virus through the body and the initiation of the immune response occurred. Monkeys that developed a rash after infection with variola virus by the respiratory route probably provided the best model system, but monkeys are expensive

animals and such experiments could only be undertaken in microbiologically highly secure laboratories. For want of a better alternative, therefore, most investigations that are relevant to an understanding of the pathogenesis of smallpox have been carried out with other orthopoxviruses, especially mousepox virus, since so much is known of the genetics and immune response in mice. But mice are not men and mousepox is not smallpox. Arguments by analogy must therefore be developed cautiously. The results of these diverse investigations will be summarized in this chapter, and the information collated to provide an integrated picture of the pathogenesis and immunology of smallpox.

Following the analysis of the pathogenesis of smallpox, we proceed to a description of the pathology and histopathology of smallpox and vaccinia, which have been studied with material from autopsies on fatal cases and, in a few cases, by taking biopsies from skin lesions. Most of this work was carried out early in this century; the most recent and most comprehensive descriptions of the pathology and histopathology of smallpox were published by Bras (1952a,b).

Finally, this chapter presents an account of the immune responses in smallpox and vaccinia, which provides the rationale of the use of the tool that made the eradication of

smallpox possible—Jennerian vaccination. Immunological intervention designed to prevent human diseases began in the 10th century, with variolation, and entered a new "scientific" phase when vaccination against smallpox was introduced in 1798 (see Chapter 6). Over the past three-quarters of a century an enormous literature has accumulated describing the mechanisms by which vaccination induced immunity to smallpox. Unfortunately, because methods of studying cellular aspects of immunity were developed relatively recently, most of these investigations were concerned only with humoral immunity. In spite of its long history, the immunology of both smallpox and vaccination against it are still imperfectly understood.

### THE PORTAL OF ENTRY OF VARIOLA VIRUS

Infection with variola virus occurred via the respiratory tract, by inoculation through the skin, or, rarely, via the conjunctiva or the placenta.

#### The Respiratory Tract

Epidemiological evidence indicates that the usual mode of entry of variola virus was via the respiratory tract and that excretions from the mouth and nose, rather than scab material, were the most important source of infectious virus. In theory, infection by inhaled virus could have occurred via the mucous membranes of the mouth, the nasal cavity, or the oro- or nasopharynx; or via the alveoli of the lungs. However, careful study of these sites in fatal cases of smallpox failed to disclose any evidence of a "primary lesion" there. Nor were patients infectious before the enanthem appeared, at the end of the incubation period. It seems, therefore, that the primary infection in the mouth, pharynx or respiratory tract did not produce a sizeable lesion nor did the lesion of infection ulcerate and release virions on to the surface.

In the absence of data from human smallpox it is pertinent to look at an animal model. Observations by Roberts (1962a) on mousepox suggest a possible sequence of events. Fluorescent-antibody staining of sections taken after exposure of mice to aerosol infection showed that the first cells to be infected were mucosal cells of the upper and lower respiratory tract and alveolar macrophages.

Virus did not spread beyond the respiratory tract until the 3rd day after infection, when it was found in free macrophages in the draining lymph nodes. At no stage did a substantial "primary lesion" develop in the respiratory tract, like that found, in both mousepox and smallpox, after infection by cutaneous inoculation.

#### Inoculation Smallpox

The clinical picture of inoculation smallpox, which sometimes occurred accidentally but was usually due to variolation by the cutaneous route, is described in Chapters 1 and 6 (see Plates 6.1–6.3). A local skin lesion appeared by the 3rd or 4th day. Fever and constitutional symptoms began on the 8th day, and the rash, which was usually much less severe after variolation than in naturally acquired smallpox, appeared on the 10th or 11th day. Thus the incubation period appeared to be 2–3 days shorter than in "natural" smallpox (see Chapter 1, Fig. 1.3). Observations on mice infected with mousepox by scarification (Roberts, 1962b) suggest that the shorter incubation period may have been due to the fact that after dermal infection infected macrophages were transported to the local lymph nodes and thus to the circulation within the first 24 hours, whereas after respiratory infection viral dissemination by macrophages was delayed until the 3rd day. Viraemia and rash would therefore occur a few days earlier after dermal infection.

#### The Conjunctiva

If infection via the conjunctiva occurred at all in smallpox, it was very rare (Rao, 1972). However, Kempe et al. (1969) noted that occasionally variolous conjunctivitis, confirmed by viral isolation, occurred at or even before the onset of the pre-eruptive fever. In no case was the interval between conjunctivitis and rash as long as that found between the appearance of the primary lesion and the rash in inoculation smallpox, which makes it difficult to decide whether the conjunctiva was actually the portal of entry.

#### Congenital Infection

Variola major was always severe in pregnant women (see Chapter 1). In Rao's (1972) series, abortions or stillbirths occurred in

35% of those in whom pregnancy terminated and observations were possible. The majority (55%) of 113 babies born in hospital died within 15 days, usually within 3 days. Congenital smallpox was recognized in only 10 of these, but some children may have died before a rash appeared. Nevertheless, at least half of the babies did not acquire infection *in utero*.

Being so much milder than variola major, cases of variola minor in pregnant women provided better data on congenital infections. There were 150 pregnant women in Marsden's (1936) series of 13 686 cases of variola minor. Only 6 abortions are known to have occurred, but Marsden thought that smallpox sometimes played a part in the induction of labour during the last 2 months of pregnancy. Sixteen women were confined in the smallpox hospital and bore 16 live infants (including 1 pair of twins) and 1 stillborn fetus with a papulo-vesicular eruption. Twenty-seven women were delivered of live infants just before admission to hospital, labour having begun at the time of the pre-eruptive fever. Marsden & Greenfield (1934) reported an analysis of 34 of the cases concerned. In 17 cases the baby escaped *in utero* infection. In 2 of these babies, born during the mother's convalescence, the vaccination did not take; the rest were successfully vaccinated, but 4 of them later contracted smallpox. Only 2 of the 17 babies who contracted variola minor *in utero* died. The course of the disease was never coincident in mother and baby; symptoms in the baby usually occurred 9–11 days after those in the mother, an interval similar to the incubation period of inoculation smallpox. The fetus was presumably infected by the growth of virus in the placenta, which would have been infected during the stage of secondary viraemia (see below).

Observation of a laboratory model (pregnant mice infected with an attenuated strain of mousepox virus) revealed that the placentas were infected and the virus grew extensively in the fetuses (Mims, 1969). Some live births occurred, but all such mice had widespread lesions which proved lethal, although the mothers had suffered only a mild disease.

### THE SPREAD OF INFECTION THROUGH THE BODY

The only sources of virus accessible for study in human smallpox during the incubation period were various secretions of contacts of cases, some of whom ultimately

got smallpox, so that in order to study the spread of infection through the host it was necessary to use animal models. Four such models have been studied: mousepox in mice, rabbitpox in rabbits, and monkeypox and smallpox in monkeys and apes.

### Mousepox

The pioneering work on the pathogenesis of generalized orthopoxvirus infections, which provided a model that proved useful in understanding the pathogenesis of chickenpox (Grose, 1981) as well as that of smallpox, was carried out with mousepox (Fenner, 1948a,b). Mice that did not die from acute viral hepatitis developed a generalized pustular rash (Fenner, 1948c) and the symptoms of the naturally occurring disease could be reproduced by the footpad inoculation of mice with a small dose of virus.

The course of events after footpad inoculation was followed by sacrificing mice at frequent intervals and titrating the viral content of certain organs—the inoculated foot, the regional lymph node, the spleen, the skin, and the blood. The results indicated that the sequence of events during the incubation period in mousepox followed a consistent pattern (Fig. 3.1). If the appearance of the primary lesion was taken as the end of the incubation period, it was evident that this symptom-free period was occupied by a complex series of events in which the virus passed in a stepwise fashion through the body: infection, replication, and liberation—usually accompanied by cell necrosis—first at the site of inoculation, then in the regional lymph node, and then in the deeper lymph nodes or perhaps directly into the bloodstream. It seems from the work of Mims (1964), who used fluorescent-antibody staining to identify virus-infected cells, that in the liver and spleen the phagocytic cells were the first infected. When infection had breached the macrophage barrier the virus replicated very extensively in the parenchymal cells of the liver and in the spleen, both of which usually showed semiconfluent necrosis. A day or so after infection of the spleen and liver, large amounts of virus were liberated into the bloodstream, and during this secondary viraemia focal infection of the skin, kidneys, lungs, intestines and other organs occurred. There was again an interval during which the virus replicated to reach a high titre before visible

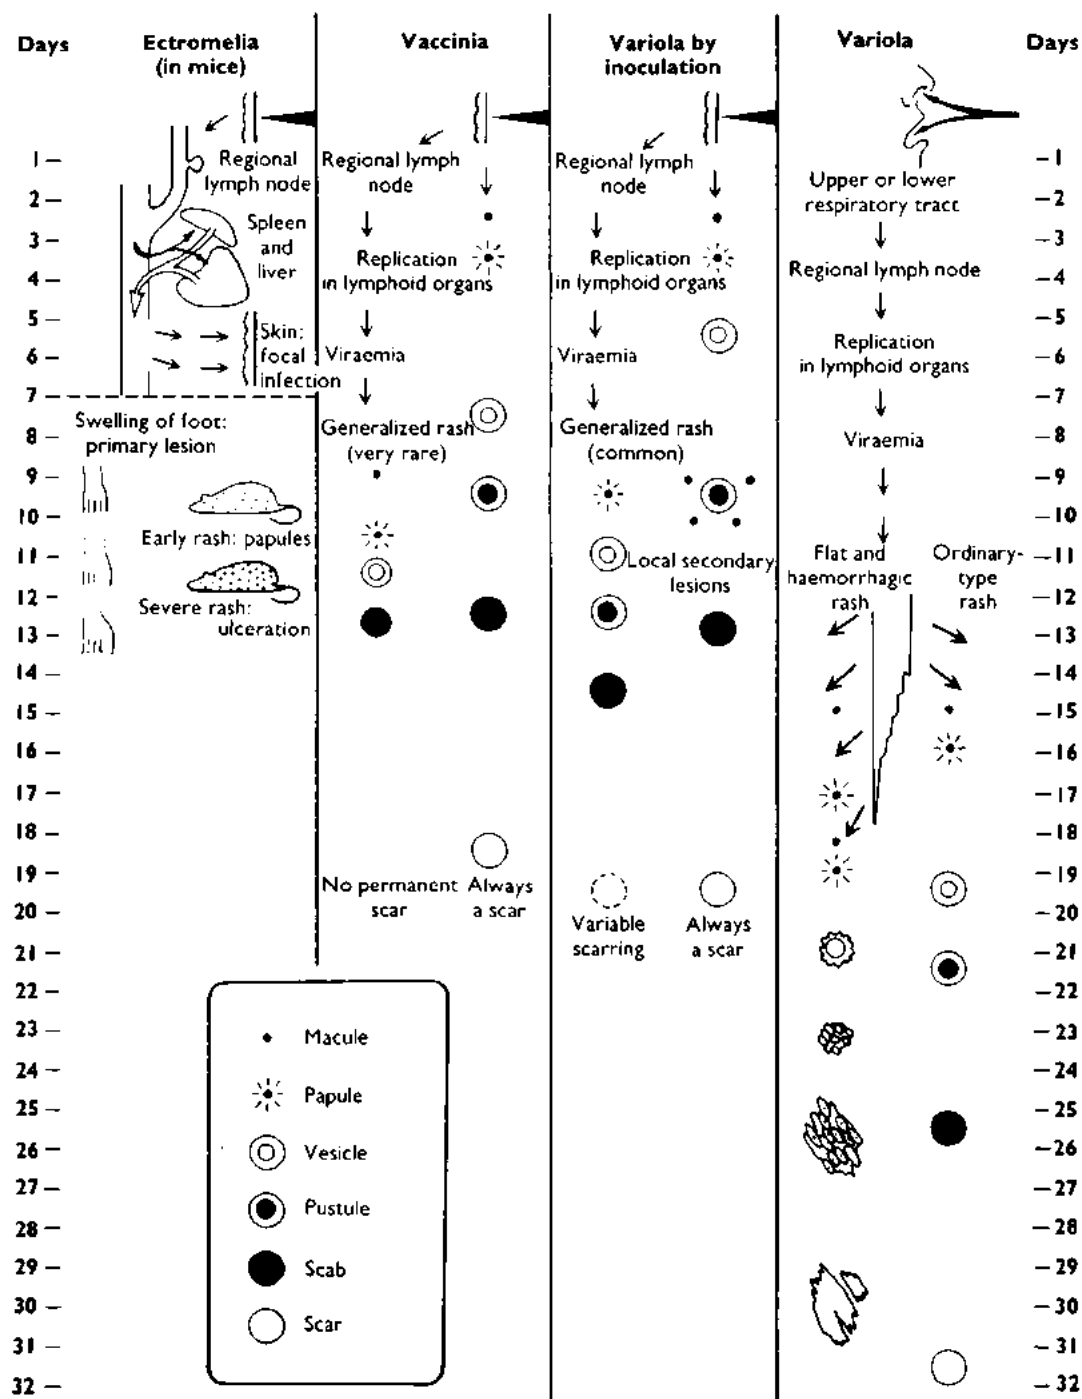

Fig. 3.1. The spread of virus around the body and the evolution and healing of skin lesions in a model system (ectromelia, after Fenner, 1948b), and in vaccinia, inoculation smallpox, and "natural" smallpox in man. For vaccinia and inoculation smallpox, the right-hand column represents lesion at site of inoculation, left-hand column represents generalized skin lesions. (Based on Dixon, 1962.)

changes were produced, so that a period of about 2 or 3 days usually elapsed between the appearance of the primary lesion and the focal lesions of the secondary rash (Fig. 3.1). The secondary viraemia was mainly cell-associated and only small amounts of virus could be recovered from plasma or serum. Mims (1964) demonstrated by fluorescent-antibody staining that circulating lymphocytes and monocytes contained viral antigen.

Although this work provided a general explanation of what happened during the long incubation period of the generalized exanthemata (Fenner, 1948b), mousepox is not a satisfactory model for smallpox. Apart from the difficulty of comparing events in mice and men, the usual mode of infection in mousepox is via skin abrasions (it is thus analogous to inoculation smallpox), rather than by the oropharynx or respiratory tract. More important, mousepox appears to be unusual among the generalized orthopox-virus infections, and certainly different from human smallpox, in that the spleen and liver are major target organs for viral replication. In mousepox these organs are clearly the "central foci", established during the incubation period, from which virus is continually released into the bloodstream, with

ensuing infection of the skin and other organs and tissues.

Subsequent research into the pathogenesis of smallpox was carried out with other laboratory models—rabbitpox and monkeypox in rabbits and monkeys respectively, and non-human primates experimentally infected with variola virus.

### Rabbitpox

Studies on the pathogenesis of rabbitpox, a severe disease of rabbits produced by certain strains of vaccinia virus, did not add much to the picture that had emerged from experiments with mousepox. After rabbits were infected by the respiratory route (Bedson & Duckworth, 1963; Westwood et al., 1966), virus spread through the body in a stepwise manner. Viral isolations could always be made from the lungs, and very high titres occurred in the gonads and the adrenal glands. The incubation period, from infection until the onset of fever, was 4–6 days. A rash usually appeared on about the 6th day, although often rabbits died before the rash became evident ("pockless" rabbitpox; Christensen et al., 1967).

In spite of the early replication of rabbitpox virus in the lung, rabbits were not infectious until nasal and conjunctival discharges appeared, and environmental contamination appeared to be maximal 6–7 days after infection. Examination by fluorescent-antibody staining revealed that after aerosol infection primary lesions developed at two distinct sites in the respiratory tract—the bronchioles and the alveoli. It was also found that as well as being spread to the bloodstream via the lymphatics, rabbitpox virus could spread directly from the bronchiolar or alveolar lesions to adjacent blood vessels.

Viraemia was mainly leukocyte-associated. Animals that died early, before the rash appeared, had viraemias which increased exponentially to reach very high titres at the time of death; those that died later had much lower titres (Westwood et al., 1966). This situation invites comparison with the levels of viraemia in haemorrhagic-type and discrete ordinary-type smallpox respectively (see below).

### Monkeypox

*Cynomolgus* monkeys are highly susceptible to monkeypox and usually develop a

c. 1960

**Plate 3.1.** Frank Fenner (b. 1914). Formerly Professor of Microbiology in the John Curtin School of Medical Research of the Australian National University, Canberra. He is shown here inoculating eggs on the chorioallantoic membrane, a method used for assays of orthopoxviruses and neutralizing antibodies to them, and for the differentiation of variola virus from other poxviruses.

generalized rash (Magnus et al., 1959). Wenner and his colleagues (review: Cho & Wenner, 1973) studied the pathogenesis of monkeypox in cynomolgus monkeys infected by intramuscular inoculation. These investigations confirmed that in orthopoxvirus infections of primates, as well as in those of mice and rabbits, there was a stepwise progression of infection, a generalized rash developing after viraemia had been established owing to the replication of virus in the internal organs. Prior to the development of the rash the virus replicated in the spleen, tonsils and lymph nodes, without producing extensive or severe lesions. Generalized lymphadenopathy developed in the 1st week after infection and persisted until the end of the 3rd week. Enlargement of the cervical and inguinal lymph nodes is a feature of monkeypox infections in chimpanzees (McConnell et al., 1968) and humans (see Chapter 29).

#### Variola Virus Infection in Non-human Primates

The monkey was the first animal to which variola virus was transmitted (Zuelzer, 1874) and monkeys were extensively used in early studies of cross-immunity between variola and vaccinia (Brinckerhoff & Tyzzer, 1906; Horgan & Haseeb, 1939). Experimental studies of the pathogenesis of smallpox in the cynomolgus monkey (*Macaca irus*) were carried out by Hahon & Wilson (1960) and Noble & Rich (1969). After an incubation period of about 6 days, inoculated animals usually developed a generalized rash that was sparse on the face, hands and feet—sites where the rash was usually more intense in human smallpox. After infection by aerosol, variola virus replicated in the lung, and secondary sites of replication were established in the lymph nodes before viraemia occurred. Although the study was complicated by pre-existing bronchopneumonia, Hahon & Wilson (1960) failed to demonstrate any major focus of local viral replication in the lungs even though they yielded a substantial amount of virus during the incubation period. Natural transmission to other monkeys could occur by the airborne route, with an incubation period of 8–16 days (see Chapter 30, Fig. 30.1).

Only 2 out of 109 rhesus monkeys (*Macaca mulatta*) infected by aerosol with variola major

virus died, but all developed fever on the 5th day and a rash between the 6th and 11th days (usually on the 7th or 8th day). Assay of various organs revealed high titres in the lungs and skin, with occasional isolations from the blood and spleen. Large amounts of virus were recovered from all organs tested in a monkey that died on the 11th day.

Rao et al. (1968b) showed that cortisone greatly increased the severity of smallpox in bonnet monkeys (*Macaca radiata*) inoculated intradermally with variola virus. None of 14 controls died, whereas 12 of the 16 animals given cortisone and 1 pregnant monkey died after suffering from a much more severe primary lesion and generalized rash than were seen in the control animals. Virus could be readily recovered from most of the internal organs of the cortisone-treated animals at the time of their death. This increased severity is comparable to that seen in pregnant women who contracted variola major (Chapter 1).

Orang-utans (Gispen, 1949) and chimpanzees (Kalter et al., 1979) can be naturally infected with variola virus (see Chapter 30), and may suffer a severe disease with an extensive rash (see Plate 30.1). Baboons (*Papio cynocephalus*) inoculated with variola virus by scarification developed a rather "dry" local lesion but no rash; virus was recovered from the blood, throat swabs and rectal swabs between the 4th and the 7th days after infection (Heberling et al., 1976).

#### Smallpox in Human Subjects

The 4th and 5th columns of Fig. 3.1 illustrate diagrammatically, on the basis of available data, the sequence of events in human smallpox after intradermal inoculation and after infection via the respiratory tract. Investigations in human subjects relevant to the pathogenesis of smallpox have been limited to virological and serological tests carried out in hospitalized patients or case contacts. Such studies were limited to the examination of blood, urine, and throat washings in cases after the onset of fever and throat washings from case contacts during what was potentially the incubation period. These investigations were important because they provided information that permitted arguments about the pathogenesis based on model systems to be developed with more confidence.

### Viraemia

No precise observations have been made on the distribution of variola virions among the various components of the blood in cases of smallpox; by analogy with other poxvirus infections viraemia would have been expected to be primarily cell-associated. Most assays of viraemia in smallpox were made with serum or lysed whole blood, the material being assayed on the chorioallantoic membrane of chick embryos (Downie et al., 1950, 1953, 1969b; Mitra et al., 1966).

Although viraemia must always have occurred, virus was only rarely recovered from the blood or serum from cases of ordinary-type smallpox. Downie et al. (1950, 1953) and Mitra et al. (1966) recorded one or two positive results out of many attempts in such cases and then only in the first few days of the disease. The picture in haemorrhagic-type smallpox was quite different. Virus was readily recovered from the blood of all cases and the titres were usually high, as determined by confluent lesions on the membrane (Downie et al., 1953, 1969b) or by titration (Mitra et al., 1966; Sarkar et al., 1969). In these patients viraemia usually persisted until the patient died. Downie et al. (1969b) noted that viraemia was consistently much higher in cases of early than of late haemorrhagic-type smallpox. They also examined the serum by gel-precipitation and complement-fixation tests for the presence of soluble antigens of variola virus; cases of haemorrhagic-type smallpox usually had an antigenaemia (Fig. 3.2). Complement-fixation tests revealed antigenaemia in 31 out of 46 sera tested, the level being, in general, proportional to the extent of the viraemia. The gel-precipitation test was less sensitive, revealing antigen in only 16 out of 45 sera tested, all from cases of early haemorrhagic-type smallpox with severe viraemia.

Thus haemorrhagic-type smallpox appears to have been associated with overwhelming infection and the continued release of virus into the bloodstream; in ordinary-type smallpox demonstrable viraemia was usually restricted to the pre-eruptive and early eruptive stages of the disease.

### Oral and pharyngeal secretions

Because there is no tough stratum corneum on the oral and pharyngeal mucosae, the lesions of the enanthem ulcerated very soon after their formation (see Plate 3.7), releasing

Fig. 3.2. Antigenaemia and viraemia in haemorrhagic-type smallpox. ● = early haemorrhagic type; × = late haemorrhagic type; ⊙ = vaccinated; S = survived (all other cases died). (From Downie et al., 1969b.)

large amounts of highly infectious virus into the saliva. The viral titres in throat swabs were at their maximum on the 3rd and 4th days of the disease (i.e., at the onset of the rash) and were highest, and persisted for the longest period, in the most severe cases (Sarkar et al., 1973a; see Chapter 4). In fatal cases virus was usually still present in the throat swabs at the time of death; in non-fatal cases it was found for 7–9 days after the onset of fever in discrete ordinary-type smallpox and sometimes for as long as 13 days in non-fatal confluent ordinary-type smallpox.

More important, from the point of view of pathogenesis, are reports of the recovery of virus in throat washings taken from case contacts who developed smallpox. Careful laboratory studies by Sarkar and his colleagues showed that household contacts of cases of smallpox sometimes harboured detectable amounts of variola virus in their throats. Using a single throat swab, Sarkar et al. (1973b) isolated variola virus in 34 out of 328 subjects who had been in close household contact with 52 index cases of smallpox for periods of between 4 and 8 days. Only 4 of the

34 contacts with positive throat swabs subsequently developed smallpox, the symptoms appearing 5–6 days after virus was isolated. In a follow-up study (Sarkar et al., 1974), positive results were reported in 5 out of 51 close family contacts examined, only 1 of whom subsequently developed smallpox (Table 3.1). Serial testing showed that virus could sometimes be recovered from the throats of vaccinated contacts, most of whom did not develop clinical smallpox, for as long as 10 days.

F. Huq (personal communication, 1982) confirmed Sarkar's findings, but recorded a much smaller proportion of positive results. Using a similar laboratory procedure, she found 3 positives (all in unvaccinated subjects, and all of whom subsequently developed smallpox) among 168 contacts who were examined within a week of the development of rash in the index subjects.

The finding of virus in throat swabs of contacts of acute cases is not altogether surprising; presumably virus replicating in an asymptomatic "primary lesion" in the fauces or elsewhere in the oropharynx was released into the oral secretions or could be obtained by swabbing the fauces. However, such virus as was present in the oral secretions during the incubation period was of little or no epidemiological importance. The onset of infectivity in the vast majority of cases coincided with the development of the rash and was due to the release of virus from the ulcerated surfaces of the lesions of the enanthem.

### The Dissemination of Virus through the Body

Orthopoxvirions were principally disseminated through the body in the lymph and

bloodstream as cell-associated particles, although some virus was always found free in plasma. In cell cultures, enveloped forms of vaccinia virus were more important than non-enveloped forms in the dissemination of virions over a distance (Boulter & Appleyard, 1973), as shown by the "anti-comet" test (see Plate 3.10). Payne (1980) showed that the capacity to spread to distant cells in monolayer cultures and to distant organs in the mouse was correlated with the production of enveloped virions (Table 3.2).

Unfortunately, no observations were ever made to determine whether enveloped virions occurred in infections of monkeys or human beings with variola virus, nor have such observations been reported with ectromelia or monkeypox viruses.

### THE RASH

The primary event for the production of the focal lesions of the rash in orthopoxvirus infections is the localization, in the small blood-vessels of the dermis, of virus particles that circulate in the bloodstream, either freely in the plasma or more commonly within virus-infected leukocytes. Subsequently, adjacent epidermal cells are infected and the skin lesion develops as described below.

In the infection of laboratory animals with orthopoxviruses, skin areas so treated as to promote a local inflammatory response are associated with an increased density of skin lesions (vaccinia in rabbits: Camus, 1917; ectromelia in mice: Fenner, 1948a). Numerous observations (Ricketts, 1908; MacCallum & Moody, 1921) attest to the effect of mild trauma leading to local vasodilatation on the density of skin lesions in different parts of the

### The Significance of Enveloped Virions

Viruses belonging to 10 of the 17 viral families that cause disease in humans are enveloped—i.e., their outer surface is a lipoprotein envelope consisting of cellular lipids and virus-specific polypeptides. Destruction of the envelope, for example by lipid solvents, usually completely destroys infectivity. The orthopoxviruses are exceptional in that although virions released from cells are enveloped (see Chapter 2, Plate 2.9), absence of the envelope is associated with only a slight decrease in the infectivity/particle ratio. Although non-enveloped particles, whose surface consists of the outer membrane (see Chapter 2, Fig. 2.1), have almost the same infectivity as enveloped particles and spread effectively by cell-to-cell contact, they do not spread as well around the body as do enveloped virions (Table 3.2).

Because there are two kinds of infectious particle, two kinds of neutralizing antibody can be produced which neutralize enveloped and non-enveloped particles respectively. Both kinds of neutralizing antibody are produced during all orthopoxvirus infections. Antibody that neutralizes only enveloped particles can be produced by immunization with purified viral envelopes. Antibody that neutralizes only non-enveloped particles is produced by inoculation with suspensions of particles obtained by disrupting cells and then inactivated. Neutralizing antibody to non-enveloped virions provides much less effective passive protection against generalized orthopoxvirus infections than does antibody to enveloped virions (see Table 3.5). The two kinds of particle also produce different kinds of cell-mediated immunity, cytotoxic T cells being generated only during infections and not by suspensions of inactivated virions. For these reasons inactivated vaccines provide only partial immunity in experimental animals and have proved useless for vaccination against smallpox.

body in smallpox (the "garter" effect). Vaso-dilatation due to sun and wind may have played a part in the greater density of lesions on the face and the extensor surfaces of the hands and arms than elsewhere on the body, but this factor does not explain the highly characteristic "centrifugal" distribution of skin lesions in smallpox, for which no satisfactory physiological explanation has yet been provided.

### TOXAEMIA

All clinical observers have commented on the "toxic" appearance of patients with variola major, especially those suffering from flat-type or haemorrhagic-type smallpox. Although very severe cases did occur—extremely rarely—in variola minor, there was usually a great contrast in the general appearance and condition of patients with variola major and variola minor with approximately the same numbers of pustules. The patient with acute variola major was usually very sick, whereas the patient with variola minor of apparently similar severity (in terms of the

number of skin lesions) might well be ambulant.

No adequate explanation is available to elucidate either the toxæmia of variola major or the difference in severity between cases of variola major and variola minor with rashes of similar extent. Viral antigen was readily demonstrable in the plasma of patients with severe smallpox (Downie et al., 1953, 1969b; see Fig. 3.2). The formation of immune complexes between such antigens and IgM antibodies, and the associated activation of complement, might have initiated a series of physiological effects that produced the so-called "toxic" symptoms of variola major.

Seeking an explanation of the cause of death in smallpox, Boulter et al. (1961a) examined various physiological parameters in a model system—rabbitpox. The only consistent physiological changes observed in sick rabbits were extreme hypotension, leading to a shock-like syndrome, decreased urinary output and a rise in blood-urea and plasma-potassium levels. Death seemed to be due to lethal concentrations of potassium ion, which occurred possibly as a consequence of the severe hypotension. No information is avail-

## PATHOLOGICAL ANATOMY AND HISTOLOGY OF SMALLPOX

### General Observations

As described in the appropriate chapters of this book, a wealth of information about the virology, epidemiology and control of smallpox has emerged from the work carried out since the inception of the Intensified Smallpox Eradication Programme in 1967. However, what Bras (1952a) pointed out more than 30 years ago was still true at the time of global eradication: in recent years smallpox usually occurred, on a large scale, in places where pathological studies were difficult. Prior to Bras's own important work one has to go back to Councilman et al. (1904) for a comprehensive description of the pathological anatomy and histology of smallpox. Some years later Lillie (1930) produced a review of published reports on the histopathology of smallpox and vaccinia. A useful description of the histology of the skin lesions in variola major was provided by Michelson & Ikeda (1927), while MacCallum & Moody (1921) and Jong (1956) obtained skin biopsies from patients suffering from variola minor.

In earlier studies interpretation of the pathological changes, particularly in the

lungs, was complicated by the presence of secondary infection with streptococci and other organisms (see Councilman et al., 1904). More recent observations have shown that although bacterial infection did sometimes complicate smallpox, pustulation was viral and not bacterial in origin, and the high mortality of variola major was due to viral effects, not secondary bacterial infection. The case-fatality rate was not significantly reduced by the use of antibiotics. Bacterial complications were rare in the cases described by Bras (1952a), most of which were treated with antibiotics.

A striking feature of the pathology of smallpox is that although it was a generalized disease, often of great severity, specific pathological changes were in large part limited to the skin and mucous membranes, except for the widespread haemorrhages found in various organs in early haemorrhagic-type smallpox.

### The Skin Lesions

In order to understand the histopathology of the skin lesions in smallpox it is necessary to appreciate the relationships between different parts of the skin, as illustrated in Fig. 3.3. The epidermis, where the pustule develops, contains no blood or lymphatic vessels and its tough outer layer, the stratum corneum, is impermeable to viruses. The dead

**Plate 3.2.** Gerrit Bras (b. 1913). Professor of Pathology at the National University in Utrecht, Netherlands. Bras carried out a classical study of the pathological changes in variola major during the epidemic in Java after the Second World War.

keratinized cells of the stratum corneum are continually being rubbed off and replaced from below, cell multiplication occurring in the stratum germinativum, which is separated from the dermis by a thin basement membrane. Of the three appendages of the skin—hair follicles, sweat glands and sebaceous glands—only the last are destroyed by variola virus, and then, to any extent, only by variola major virus.

The appearance of the skin lesions, their temporal development and their characteristic distribution are described and illustrated in Chapter 1. The following description of the histology of the skin lesions at various stages of the disease draws mainly on postmortem material from variola major described by Michelson & Ikeda (1927) and Bras (1952a,b) and biopsy material obtained from cases of variola minor (MacCallum & Moody, 1921; Jong, 1956).

#### *Early changes in the dermis*

Bras (1952a) noted that the histological picture in the skin lesions in all types of variola major, whether haemorrhagic or not, was essentially the same. The development and evolution of a skin lesion are shown in Plate 3.3. The earliest change was a dilatation of the capillaries in the papillary layer of the

**Fig. 3.3.** The structures of importance in the pathogenesis of the skin lesions of smallpox. The epidermis consists of several layers of living cells, the stratum Malpighii, covered by a layer of dead keratinized cells, the stratum corneum (A). The basal layer of the stratum Malpighii consists of dividing cells, the stratum germinativum (D), above which there is a variable number of layers of cells, called the stratum spinosum (C), and just below the stratum corneum a layer of cells that contain keratohyalin granules, the stratum granulosum (B). The dermis contains blood vessels (V), lymphatic vessels (L) and fibroblasts and macrophages (FM). The ground substance contains collagenous, reticular, and elastic fibres. The hair follicle (HF) and sebaceous gland (SG) are appendages of the epidermis.

dermis, followed by swelling of the endothelial cells in the walls of these vessels, stasis of mononuclear cells within the lumen, and subsequently perivascular cuffing with lymphocytes, plasma cells, macrophages and occasionally eosinophilic granulocytes (Plate 3.3A). Biopsies from cases of variola minor (MacCallum & Moody, 1921) showed that the affected papillae were oedematous, with extravasation of erythrocytes and leukocytes, at a time when the overlying epidermis was unchanged or showed at most only an early vacuolation of the epidermal cells.

#### *Epidermal changes*

Following the early changes in the dermal vessels, lesions developed in the adjacent part of the epidermis, where all subsequent changes occurred. The cells of the stratum Malpighii became swollen and vacuolated and underwent what was described as "ballooning" degeneration. This occurred in a sharply demarcated area and only a small number of cells separated the centre of the lesions from the surrounding normal skin (Plate 3.3A and B). The degenerated cells were swollen, they stained faintly with acid dyes, and the characteristic B-type inclusion bodies (Guarnieri

bodies: see Chapter 2, Plate 2.7) could be found in the cytoplasm.

Early in the disease, in sections stained with haematoxylin and eosin, the inclusion bodies appeared as round or oval homogeneous faintly basophilic or acidophilic masses lying close to the nucleus. One or more were present in a cell and each was usually surrounded by an unstained halo. In older lesions the inclusions had a granular appearance and irregular outline and sometimes occupied a large part of the cytoplasm of infected cells. Intranuclear inclusions have also been described in cells infected with variola virus (Torres, 1936), but not with other orthopoxviruses. They were not a conspicuous feature of the lesions, but Downie (1965a) confirmed that they did sometimes occur. Their significance is unknown.

The cells continued to increase in size, the cytoplasm became fainter and the nucleus usually disappeared by lysis. Soon after this the cell membranes ruptured and the vacuoles coalesced to produce the early vesicle by what was called "reticulating" degeneration (Plate 3.3C). Because this coalescence occurred very quickly a true papule was rarely seen; almost from the beginning the lesion was already vesicular.

### *Vesiculation*

The reticulating degeneration which produced the vesicle occurred exclusively in the middle and upper layers of the stratum spinosum; the basal cells were at first unaffected and the keratohyalin and horny layers showed no changes. Subsequently the cells of the lower stratum spinosum and the basal layer underwent a different kind of degeneration; the nuclei and cytoplasm became condensed, the cells became hyalinized and the nuclei fragmented or lysed. Later these basal cells disappeared and the cavity of the vesicle (or pustule) was then immediately adjacent to the dermis.

The fully developed vesicle (Plate 3.4) resembled a plano-convex lens with the following characteristics:

(1) The roof, which was very thin over the summit of the vesicle, consisted of compressed cells of the stratum spinosum, keratohyalin layer and horny layer.

(2) The base consisted at first of cells of the stratum spinosum and basal layer, which showed a hyaline fibrinoid degeneration,

becoming swollen, homogeneous and refractile, losing their granular character and staining more intensely with acid dyes. Later they lysed, so that the base of the vesicle was provided by the subjacent dermis.

(3) Since a portion of the cytoskeleton persisted for a long period after the degeneration of the cells of the stratum spinosum, the cavity of the vesicle contained incomplete septa, creating a multiloculated appearance (Plate 3.4A). Such loculation was never complete. Often there were heavier septa, which were made up of the coils of sweat glands traversing the cavity. Like the keratohyalin cells in the roof of the vesicle, the cells of sweat glands appeared resistant to the effects of variola virus.

(4) Fluid accumulated inside the vesicle, with threads of fibrin and a few lymphocytes.

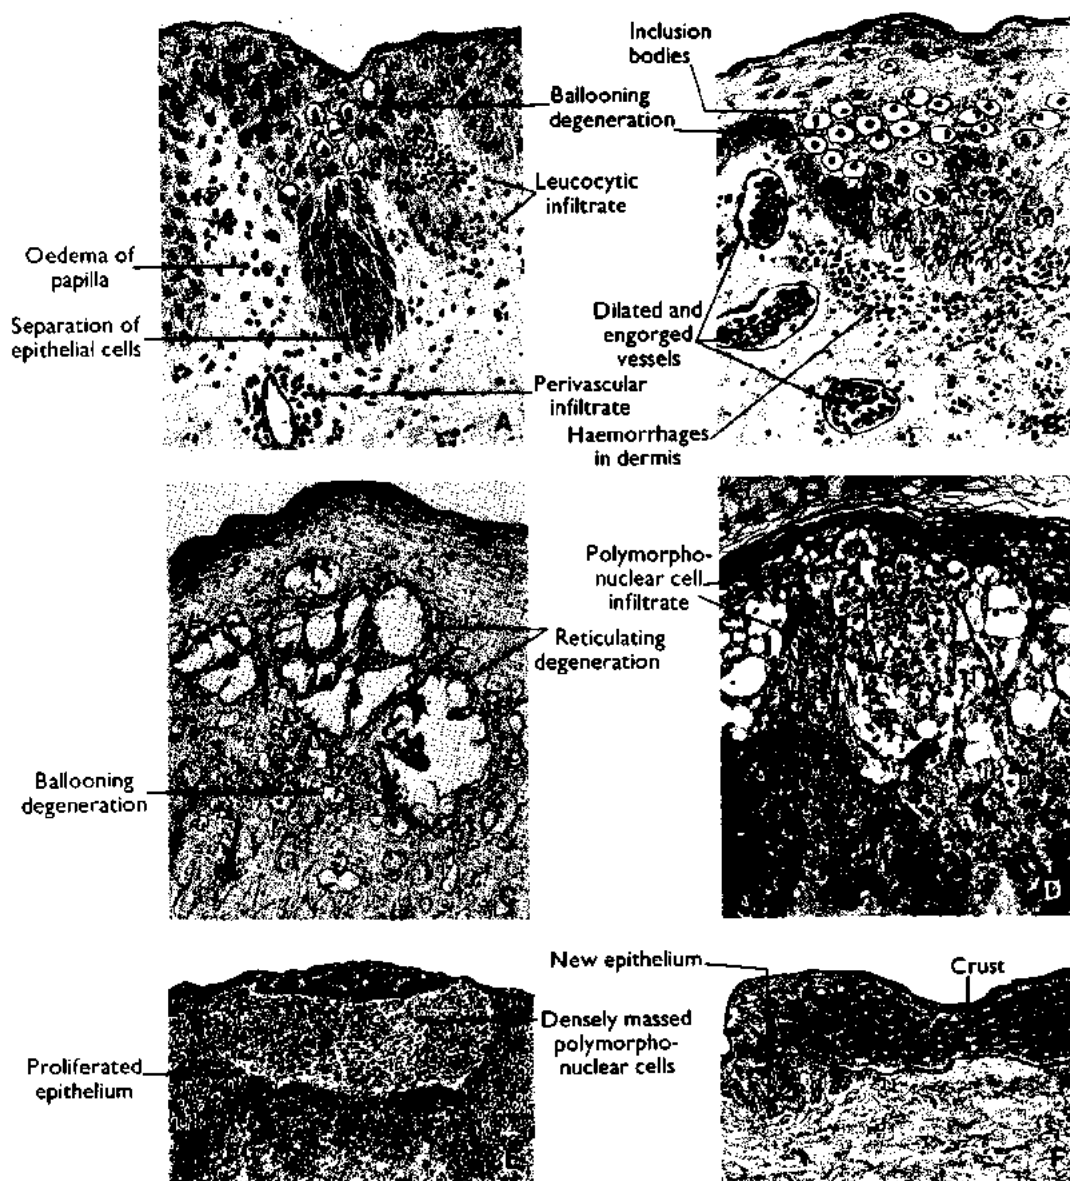

(5) The cells immediately around the vesicle showed decreasing degrees of reticulating degeneration and the basal layers had often proliferated, so that the wall around the vesicle was about twice the thickness of the unaffected epidermis. The rete pegs in the area adjacent to the vesicle were relatively deep.

### *The pustule*

Pustulation occurred by the migration of polymorphonuclear cells from the subpapillary vessels into the vesicle, the dermis being relatively free of such cells (Plate 3.3D and E). This response was not due to secondary bacterial infection; numerous investigations showed that pustules containing abundant leukocytes were bacteria-free. Councilman et al. (1904) commented on the absence of polymorphonuclear leukocytes and the abundance of plasma cells in the adventitial sheaths of the vessels in the dermis as pustulation occurred—evidence of the rapidity and extent of the immune response in ordinary-type smallpox. Unfortunately, the literature lacks descriptions of the histopathology of flat-type smallpox. In such cases one might have expected to find a much less vigorous cellular response at this stage of the disease.

### *Umbilication*

Except on the palms and soles, umbilication was a common feature of the skin lesions in smallpox (see Chapter 1, Plate 1.10). It was apparent quite early, then partially disap-

**Plate 3.3.** Stages in the development and evolution of the skin lesion. **A:** The earliest change was oedema of the dermis leading to the separation of epithelial cells of the papillae and lymphocytic infiltration in the dermis, especially around the small vessels. Ballooning degeneration was seen in a few cells in the lower Malpighian layer. **B:** These changes progressed and the small vessels became dilated and engorged. Inclusion bodies were also visible adjacent to cells showing ballooning degeneration. In early haemorrhagic-type smallpox, illustrated here, there was pronounced haemorrhaging into the dermis. **C:** As the pathological process progressed, the epithelial cells broke down by reticulating degeneration to produce a multilocular vesicle. **D:** The vesicle formed by coalescence of the smaller cavities became infiltrated with polymorphonuclear leukocytes to produce a pustule, around which were cells containing inclusion bodies. **E:** The fully developed pustule became packed with polymorphonuclear leukocytes and the epithelium on either side of the pustule proliferated. **F:** Eventually the pustule became a crust, beneath which new epithelium grew in to repair the surface. Such lesions, in which the sebaceous glands were not involved, healed without leaving a pockmark. (From Michelson & Ikeda, 1927.)

**Plate 3.4.** Fully developed vesicle. **A:** Loculated cavities with relatively acellular exudate formed as a result of reticulating degeneration of the middle layers of the epidermis. Unaffected keratohyalin and horny layer form the roof of the vesicle; at its base, cells are undergoing hyaline fibrinoid degeneration, which is best seen in **B**, the higher power view. Haematoxylin and eosin, **A**  $\times 130$ ; **B**  $\times 260$ . (From Bras, 1952a.)

peared and reappeared during the late stages of pustulation. Umbilication was mainly due to the swelling of the cells around the vesicle and the proliferation of basal cells surrounding the lesion, so that the periphery of the vesicle was raised above the level of its centre, as well as above the surrounding unaffected skin. Often the presence of a hair follicle within a vesicle anchored the centre part, but umbilication was also found in lesions on the lip and glans penis, where no hairs occur. The partial disappearance of umbilication was due to the increase in fluid in the vesicle; as the contents desiccated prior to healing umbilication reappeared.

#### *Scabbing*

With the development of an effective immune response, healing began. The contents of the pustule became desiccated and re-epithelialization occurred between the cavity of the pustule and the underlying dermis. The pustular contents became a crust or scab (Plate 3.3 F and Plate 3.5), which was subsequently shed; the newly formed epidermis had no rete pegs. In the absence of secondary infection, the dermis showed very few changes and in most parts of the body the lesions healed without scarring and thus without pockmarks.

In the soles and palms, where the layer of horny cells is very thick, the dried exudate remained enclosed within a mass of horny

substance for a long period if not artificially removed.

#### *Scarring*

The face bore the heaviest crop of lesions in most cases of smallpox (for example, "semi-confluent" ordinary-type smallpox was the term applied to cases in which lesions were confluent on the face but not elsewhere; see Chapter 1), and lesions usually appeared first on the face and evolved the most rapidly there. However, if the dermis was not involved such lesions should not have produced scars, yet scarring (pockmarks) was very much more common on the face than elsewhere (Ježek et al., 1978d). Bras (1952b) showed that this occurred because sebaceous glands are much larger and more numerous in the facial skin than elsewhere on the body. Although the cells of other skin appendages (hair follicles and sweat glands) were relatively unaffected by variola virus, cells of the sebaceous glands were highly susceptible (Plate 3.6). Degenerative changes began with cytoplasmic hyalinization accompanied by hyperchromatism of the nuclei, karyorrhexis and cytolysis. This degeneration occurred simultaneously in several parts of the sebaceous gland, leading to extensive necrosis in the subepithelial layer of the skin. When healing occurred, the defect in the dermis was filled with granulation tissue, which subse-

**Plate 3.5.** Scabbing. **A:** Low-power magnification; the pustule has become a crust. **B** and **C:** High-power magnification. **B:** A keratohyalin layer has developed under the outer part of the pustule. **C:** Recovery is at an earlier stage in the centre; later the keratohyalin layer extends beneath the entire crust. Lesions like this left no scar. (From Bras, 1952a.)

**Plate 3.6.** Section through pustule on the face; 5th day of rash. **A:** Low-power magnification; there is severe involvement of the subepidermal tissue through necrosis of the large sebaceous glands. **B:** High-power magnification; focus of disintegration in the sebaceous gland are indicated by arrows. Scarring would occur due to fibrosis in the dermis, leading to the formation of a facial pockmark. Haematoxylin and eosin. **A**  $\times 50$ ; **B**  $\times 225$ . (From Bras, 1952b.)

quently shrank, leaving localized facial pockmarks.

Descriptions of the histopathology of the skin lesions in variola minor do not include material from the face, since biopsies would be difficult to obtain from this part of the body. It is reasonable to suggest that the rarity of facial pockmarks after variola minor (Ježek & Hardjotanojo, 1980) was due to the failure of variola minor virus to cause the necrosis of cells of the sebaceous glands.

#### *Specific effects of early haemorrhagic-type smallpox*

Twenty-three of the 177 cases studied by Bras (1952a) were of early haemorrhagic-type smallpox. In these cases the major difference from the skin lesions just described was the much more extensive hyperaemia of the dermal vessels, which affected the deeper plexuses as well as the subpapillary network. There were also haemorrhages between the collagen fibres of the dermis (Plate 3.3B), and occasionally into the papillae and even the epidermis. Usually the patient died before vesiculation or pustulation occurred. Early reticulating degeneration was usually present in the epidermal cells, which contained large vacuoles. Guarnieri bodies were numerous. The skin lesions were usually extremely diffuse, so that often no normal skin could be found over large areas of the body surface.

#### *Specific effects of late haemorrhagic-type smallpox*

Although the skin lesions often seemed to be haemorrhagic pustules (see Chapter 1; Plate 1.23C), histological examination showed that bleeding usually occurred in the dermis beneath the pustule, although some vesicles and pustules did contain erythrocytes.

### **Lesions of the Mucous Membranes of the Respiratory and Digestive Tracts**

In contrast to the skin, in which the evolution of vesicles and pustules was obvious, the lesions of various mucous membranes were less easily observed.

#### *Gross findings*

The mucous membranes on which varicellous lesions occurred were, in descending order of frequency, the pharynx and uvula (see Chapter 1, Plate 1.3 C), the larynx, the

tongue, and the upper part of the trachea and oesophagus (Bras, 1952a). Lesions of the lower part of the trachea and the bronchi were much less frequent, and they were rarely found in the intestines, except for rare cases of haemorrhagic-type smallpox in which the mucous membrane of the lower rectum was shed as a large slough (see Chapter 1). The mucosal lesions evolved more rapidly than those in the skin; healing was usually complete by the end of the 2nd week of illness.

In general, the mucosal lesions of haemorrhagic-type smallpox were similar to those of ordinary-type smallpox in localization and character, except for the more pronounced submucosal haemorrhages. If, as sometimes happened, such patients died soon after the appearance of the skin lesions, the pharyngeal mucosa did not show any gross lesions but was smooth and glistening, with submucosal haemorrhages.

In patients dying at a later stage there was often an adherent pseudomembrane on the lateral wall of the pharynx, which when torn off revealed a haemorrhagic-hyperaemic base. Similar pseudomembranes were found—more rarely—on the epiglottis and larynx, but localized lesions sometimes occurred in the trachea. Ulcers also formed on the tongue, although they were often difficult to see because of the pleats and folds of that organ. Very rarely, circumscribed lesions were found on both surfaces of the intestines.

#### *Histopathology of mucosal lesions*

Although showing a general resemblance to the lesions found in the skin, the pathological process in mucous membranes was modified by the nature of the tissue: epithelial cells in mucous membranes are not so tightly packed together as in the skin, and there is no horny layer which might have contained the developing vesicle. There was also a more pronounced exudation of fluid into the sub-epithelial tissues.

The earliest change in the mucous membranes appeared to be exudation into the epithelium, leading to separation of the cells, which underwent hyaline fibrinoid degeneration. Guarnieri bodies were numerous and numbers of superficial cells were exfoliated from an early stage of development of the lesion. Instead of a vesicle, the extensive necrosis in the epithelial cells, unrestrained by a horny layer, led to early ulceration (Plate 3.7). The base of the necrotic mass of cells was

**Plate 3.7.** Ulcer on oral mucous membrane. The pustule ulcerates because there is no overlying horny layer. (From Michelson & Ikeda, 1927.)

sharply outlined against the hyperaemic tunica propria. Occasionally the tunica propria showed patchy necrosis unrelated to the superficial defects. Later there was increasing vascularization under the tunica propria and the tissue took on the appearance of granulation tissue, with numerous polymorphonuclear leukocytes in the demarcation zone beneath the necrotic epithelium. This combination produced the pseudomembrane observed macroscopically, which could be easily detached. Because of the numerous bacteria on the mucous membrane of the pharynx the necrotic lesions were usually found to harbour masses of bacteria of various kinds, but this was a secondary phenomenon.

Since the mucosal lesions, especially those of the oropharynx, were the major source of infectious virus in smallpox, it is important to note the time relationships between the development of mucosal and skin lesions. The mucosal lesions appeared during the early papular stage of the rash and had usually healed, without scarring, by the end of the pustular stage.

Although the oropharynx or the respiratory tract is usually regarded as having been the portal of infection in smallpox, no writer has described lesions in the oropharyngeal mucosa, or anywhere in the respiratory tract, which might be regarded as "primary" lesions. The diffuse oropharyngeal lesions, like the circumscribed lesions found on the tongue and uvula, appeared at the same time as the earliest lesions in the skin. There appears to be

no reason to doubt that the focal mucosal lesions, like those of the skin, were haemato-genous in origin. By analogy with mousepox and rabbitpox, small, non-destructive primary lesions may have occurred in the oral cavity, pharynx or respiratory tract in smallpox, but they would have been impossible to recognize without recourse to a selective staining method such as fluorescent-antibody staining.

### Effects on Other Organs

Death was due to viral toxæmia, exacerbated by clotting defects in haemorrhagic-type smallpox. Antibiotics were usually given to all patients in the Madras Infectious Diseases Hospital from the 1950s onwards (A.R. Rao, personal communication, 1981). Such treatment reduced the case-fatality rate by 5–10% in vaccinated subjects, compared with those not given antibiotics, but had no effect on the outcome among unvaccinated patients.

Councilman et al. (1904), Lillic (1930) and Bras (1952a) each described the gross and microscopic appearances of the various internal organs in fatal cases of smallpox. The striking feature about all these reports was the absence of specific lesions anywhere except in the skin and mucous membranes. Readers should refer to these papers for detailed descriptions; comment here is focused mainly on pathological findings that might have been of significance in the pathogenesis of smallpox. Probably the most important change from this point of view was the involvement of the reticuloendothelial system, noted in particular by Bras (1952a).

#### *Reticuloendothelial system*

The endothelial cells lining the sinusoids of the liver were often swollen and occasionally proliferating or necrotic. Such changes were most commonly found in individuals who died very early in the course of the disease; Bras suggests that they may have been even more prominent during the pre-eruptive stage. Reticulum cell hyperplasia occurred in the bone marrow and spleen. In addition, the spleen was usually engorged and contained very numerous large lymphoid cells, the morphological sign of a developing immune response. Few specific changes were found in

the lymph nodes, except for small necrotic foci in those of the pharynx and in the tonsils.

#### *Kidneys*

Bras (1952a) described spectacular pelvic haemorrhages in cases of early haemorrhagic-type smallpox, a finding which is in accordance with the frequent occurrence of haematuria in these cases.

#### *Testes*

Small foci of necrosis occurred in various parts of the testis (parenchyma, mediastinum and epididymis); these were usually too small to be recognized macroscopically.

#### *Liver*

Most authors noted that the liver was usually considerably heavier than normal, but found it difficult to ascribe a cause for this; it did not appear to be due to engorgement or fatty infiltration. However, the parenchymal cells usually showed intense cloudy swelling.

#### *Brain*

Encephalitis was an occasional complication of smallpox, which occurred much more frequently than did postvaccinal encephalitis after primary vaccination, but it was of minor importance compared with the severe toxæmia of variola major. Encephalitis occurred more often in variola major than in variola minor, but because so few deaths ensued in the latter variety of smallpox it was relatively more important. Marsden & Hurst (1932) provided an exhaustive review of the literature and gave detailed histories of 11 cases occurring after variola minor, of which 3 were fatal. The fatal cases had brain lesions like those described for postvaccinal encephalitis (see below).

#### *Effects specific to haemorrhagic-type smallpox*

As well as the extensive haemorrhages in the skin found in all cases of haemorrhagic-type smallpox, both early and late, haemorrhages were often found in other sites, such as the gastric mucous membrane, the pelvis of the kidney, the myocardium and endocardium, and the submucosa of the pharynx and larynx.

Although megakaryocytes were numerous in the bone marrow of cases of pustular

smallpox, there were strikingly few present in the bone marrow of primary haemorrhagic-type smallpox, a finding which explains the profound thrombocytopenia and bleeding that occurred in these cases (see Chapter 1).

### THE HISTOPATHOLOGY OF VACCINIA AND VACCINIAL COMPLICATIONS

Clinical aspects of vaccination and revaccination and the complications associated with vaccination are described and illustrated in Chapter 7. Numerous studies have been carried out on the histology of cutaneous changes in vaccinated calves and rabbits (reviewed by Lillie, 1930) but few studies have been made in man. The most important complication of vaccination, postvaccinal encephalitis, has been studied by many investigators, but its pathogenesis remains obscure.

#### Normal Vaccination

The aim of vaccination was to bring vaccinia virus into contact with cells in the Malpighian layer of the epidermis. After primary vaccination a papule developed in 3–5 days, rapidly became a vesicle and later became pustular, reaching its maximum size after 8–10 days (see Fig. 3.1). A scab was then formed, which separated at 14–21 days, leaving the typical vaccination scar.

Vaccination produced a generalized infection in man, with swelling and tenderness of the draining lymph nodes and a viraemia sometimes detectable between the 3rd and the 10th day after vaccination, most frequently on the 6th day (Herzberg-Kremmer & Herzberg, 1930a,b; Siegert & Schulz, 1953). Gins et al. (1929) recovered vaccinia virus from tonsillar swabs taken 3, 4 and 5 days after vaccination, and Gurvich et al. (1979) reported the isolation of vaccinia virus from the pharyngeal swabs of 49% of children with postvaccinal tonsillitis between the 7th and the 15th day after vaccination, compared with 7% of children with uncomplicated vaccinia and no evidence of pharyngitis. The level and persistence of detectable viraemia were dependent on the strain of virus used; it was regarded as rare and transient by Blattner et al. (1964) and Kempe (1960), who used the mild New York City Board of Health strain. More

prolonged viraemia occurred in children with immunological deficiencies (Keidan et al., 1953), some of whom suffered from progressive vaccinia.

#### *Changes in the skin*

Howard & Perkins (1905) studied the histological appearance of vaccination lesions in biopsies taken from 12 subjects. The earliest changes were cytoplasmic and perinuclear vacuolation in the epithelium, accompanied by cloudy swelling, coagulation necrosis, intercellular oedema and vesicle formation. Within 48 hours, a cup-shaped vesicle traversed by an eosinophilic reticular network had appeared, of which the stratum corneum formed the roof, and the floor, centrally, was bare dermis. At the sides were cells in hyaline degeneration, which were intensely eosinophilic, with shrunken pyknotic nuclei. There were marked oedema of the papillae and free erythrocytes, mononuclear and polymorphonuclear cells, as well as perivascular infiltration. Subsequently, leukocytes invaded the vesicle, and the necrosis of epithelium and leukocytes produced a crust of dense, homogeneous, deeply staining reticulum. Guarneri bodies were present in the epithelial cells. Epithelial outgrowth occurred beneath the crusts.

In progressive vaccinia the primary vesicle failed to heal and the usual lymphocytic infiltration failed to occur because the persons involved had defective cell-mediated immune responses. In one such case, Keidan et al. (1953) noted that germinal centres and lymphocytes were completely absent from the axillary lymph node and spleen of the patient, although many plasma cells were present (Plate 3.8).

#### *The draining lymph nodes*

Successful primary vaccination produced moderately enlarged, painful regional lymph nodes. This reaction was first apparent on about the 5th day as the skin lesion became vesicular, and most pronounced on about the 10th day. The lymph nodes often remained enlarged and tender for 2-4 weeks after the skin lesion had healed.

In 2 persons who had been killed in an accident while at the height of a primary vaccinal reaction, it was noted (W.E.D. Evans, unpublished observation, 1960—cited by Symmers, 1978) that the axillary lymph

**Plate 3.8.** Section of a vesicle produced in human skin by vaccinia virus inoculated in a child who developed progressive vaccinia. There are no inflammatory cells in the dermis. (From Keidan et al., 1953.)

nodes showed marked follicular hyperplasia with large germinal centres. There was a conspicuous proliferation of large pale cells among the lymphocytes of the cortical and paracortical regions—morphological indicators of an active immune response—and Guarneri bodies were seen in one case.

A rare sequel of vaccination, persistent lymphadenitis, was sometimes confused with lymphoma if biopsies were performed for the diagnosis of painless lymphadenopathy. Hartsock (1968) records that a diagnosis of malignant lymphoma was mistakenly made in 9 out of 20 such cases; all eventually subsided completely. The lymph nodes in these cases showed diffuse or follicular hyperplasia, an increased number of reticular lymphoblasts, which gave a mottled appearance to the sections, and a mixed cellular response, with varying numbers of eosinophils, plasma cells and mast cells. The morphological changes in

the lymph nodes indicate a vigorous immune response to vaccinia infection.

### Postvaccinal Encephalitis

The incidence and clinical features of this rare but important complication of vaccination are described in Chapter 7. Postvaccinal encephalitis (or encephalomyelitis) is characterized by acute perivascular demyelination. Similar lesions sometimes occurred after smallpox (Marsden & Hurst, 1932). Postinfection encephalitis is a well-recognized complication of measles and varicella and a similar disease sometimes occurs after vaccination against rabies. One case has been recorded as a complication of cowpox in a human being (Verlinde, 1951). The histopathology of postinfection and postvaccination encephalitis, from whatever cause, is identical.

Although Kaiser & Zappert (1938) noted that 35 cases of disease of the central nervous system were recorded among 10 090 persons vaccinated in Bohemia in 1801 and 1802, postvaccinal encephalitis was not recognized as a serious problem until the 1920s. The first clear account of the clinical picture and histological changes was given by Turnbull & McIntosh (1926). After that time physicians became more aware of its occurrence and postvaccinal encephalitis presented a serious problem, especially in some European countries, in the period between 1930 and 1960 (see Chapter 7).

The onset of nervous symptoms, which were

predominantly encephalitic or myelitic, was abrupt and took place 10–13 days after vaccination—i.e., at a time when both the cell-mediated and humoral immune responses were well developed. A striking feature was the astonishingly rapid and complete recovery of apparently moribund subjects, but the case-fatality rate was usually between 25% and 50%.

Vries (1960) distinguished two pathological groups, which he characterized as postvaccinal encephalopathy in infants, and postvaccinal encephalitis in older persons. In infants under 2 years of age the changes seen in the brain were essentially vascular: oedema, either general or perivascular; mild lymphocytic infiltration of the meninges and some perivascular spaces; widespread degenerative changes in the ganglion cells; and sometimes perivascular haemorrhages. Older persons exhibited the features characteristic of all postinfection encephalitides, as described by Turnbull & McIntosh (1926) and reviewed by Hurst (1953). Meningeal inflammation was slight and irregular; the nerve cells were little affected; and advanced neuronophagia did not occur. The dominant feature was perivascular demyelination of the medullary sheaths, accompanied by destruction of the axis cylinders (Plate 3.9). The perivascular space contained many lymphocytes and the demyelinated areas contained lymphocytes and highly pleomorphic microglia. Conybeare (1964b) and a number of Soviet authors confirmed the differentiation between encephalopathy in

infants and postvaccinial encephalitis in older persons, although in older infants the conditions merged and early perivascular demyelination was seen.

Although vaccinia virus was occasionally demonstrable in the brain or cerebrospinal fluid (Turnbull & McIntosh, 1926), most investigators failed to recover virus from the brains of fatal cases. Kurata et al. (1977), for example, were unable to recover vaccinia virus from any of 5 reported fatal cases, or from 30 other cases examined during the previous 20 years. However, they demonstrated vaccinia antigen in the leptomeninges and, complexed with IgM, in the areas of perivascular cellular infiltration in 3 out of the 5 cases studied. The consensus is that apart from postvaccinial encephalopathy in infants, all the postinfection encephalitides, whether occurring as a result of smallpox, vaccination, measles or other viral infections, are essentially an allergic response to some viral or virus-induced antigen(s) (Johnson, 1982).

The most puzzling feature about postvaccinial encephalitis in persons over 2 years of age was the great variability in its frequency in different countries and at different times (see Chapter 7). There appears to have been some relationship between the virulence of the virus (variola or vaccinia) and the frequency of postinfection encephalitis. Rao (1972) observed frequencies of 1 in 500 variola major cases and 1 in 100 000 primary vaccinations in Madras, and Marsden (1936) 1 in 2000 cases of variola minor in London. The incidence after primary vaccination in different countries and at different times varied from 9 per million in the USA in 1968 to 1219 per million in Austria for the period 1948-1953 (see Chapter 7, Table 7.8). In several countries in which the incidence was high the rate fell substantially when the strain of virus used for vaccination was changed.

Postinfection encephalitis in smallpox and after vaccination was clearly due to an unusual host response, probably to poxvirus antigens or antigen-antibody complexes that localized in neural tissue. It is significant that postvaccinial encephalitis was almost unknown as a complication of revaccination, an observation which led to the promotion in the 1960s of a variety of schemes of "pre-immunization" in countries from which smallpox had been eliminated (see Chapter 7). The likelihood of neural localization of the relevant antigen was, in part, determined by the virulence of the virus concerned, there

being a gradation in frequency: variola major, variola minor, more virulent strains of vaccinia virus, less virulent strains of vaccinia virus.

### VIRAL PERSISTENCE AND REACTIVATION

Different viruses of vertebrates behave in characteristic ways after the host animal recovers from an acute infection, and the precise mode of behaviour has important epidemiological implications. Five situations can be distinguished:

(1) The acute infection is followed by clinical recovery and the virus is completely eliminated from the body; it cannot therefore be reactivated by immunosuppression or any other means, because it is no longer present in the host organism. Mumps and poliomyelitis are examples. The smallpox eradication campaign was undertaken on the assumption that smallpox also fell into this category.

(2) The acute infection is followed by clinical recovery but the virus persists in the body. It may be reactivated by a variety of stimuli and can then cause recurrent illness, with the shedding of virus. This is the characteristic mode of behaviour of herpesviruses—e.g., in herpes simplex, varicella-zoster and cytomegalovirus infections.

(3) The infection is followed by clinical recovery and in the vast majority of individuals the virus is completely eliminated. Occasionally, however, it may persist and cause chronic disease, but it persists in a sequestered site and is not shed, so that persistence is of no epidemiological significance. Measles, with its rare complication, subacute sclerosing panencephalitis, is a good example.

(4) The infection is usually inapparent, but virus may persist in sequestered sites for long periods without ever causing symptoms, unless it is reactivated by procedures such as renal transplantation. Certain human papovaviruses behave in this way (Gardner, 1977); they may also be reactivated and excreted in urine during normal pregnancy, with no harmful effects (Coleman et al., 1980).

(5) After the patient has recovered from the acute infection the virus persists as a chronic infection which may sometimes be associated with chronic disease. Such cases may be infectious; hepatitis B is an example.

From the point of view of the smallpox eradication programme, the question of viral

persistence was of importance from two points of view. First, if reactivation and re-excretion of virus could occur in a person who had recovered from smallpox, under any circumstances, such a person would constitute a potential source from which smallpox could re-emerge. Secondly, the likelihood of success in a search for virus in an animal reservoir of variola or monkeypox viruses is greatly influenced by whether these viruses persist in the tissues of infected animals for prolonged periods. If it occurred, persistent infection could be of epidemiological importance in human monkeypox (see Chapter 29), for persistent virus, even if it were not excreted, could be a source of infection to humans handling or eating such animals.

### Persistence of Variola Virus in Human Patients

The evidence against the persistence of variola virus in man, after recovery from infection, is strong but circumstantial; it is impossible to prove that cases of persistent infection never arose. In the whole history of smallpox, no case has occurred which could be unequivocally traced back to infection acquired from a person who had recovered from the disease months or years earlier, nor has any suspicion of the recurrence of symptoms or of the circulation of variola virus ever arisen in a person who had recovered from smallpox and subsequently undergone immunosuppressive treatment. Nor has vaccinia virus, used until recently on a large scale in Europe and North America (where immunosuppression therapies are practised more widely than in the developing countries), ever shown any indication that it could cause a latent infection in man. Since alert clinicians and virologists have recognized the occurrence of latent infections with a wide variety of viruses, and their reactivation after immunosuppressive treatment, this negative evidence is important. It is reasonable to agree with the conventional belief that variola virus belonged to the first group of viruses listed—i.e., infection was followed by death or recovery with complete elimination of the virus; persistent infection did not occur.

### Persistence of Orthopoxviruses in Animals

The evidence that some orthopoxviruses might persist for long periods after recovery

from infection in various animal species is more difficult to evaluate than the persistence of variola or vaccinia viruses in man.

#### *Mousepox*

Several authors have suggested that ectromelia virus could produce a latent infection in mice, but most examples that have been quoted could be explained as plausibly by persistent infection in the population, rather than prolonged viral persistence in individual mice. However, there are a few examples of the persistence of ectromelia virus for at least several weeks in a sequestered site in healthy mice and also of persistent infection with shedding. For example, Fenner (1948c) noted the recurrence of foot swelling, and the isolation of virus from the swollen foot, in 2 mice that had been infected 2 and 7 months earlier and had not been subsequently exposed to infection. In other experiments Fenner (1948d) demonstrated the presence of ectromelia virus in the lungs and spleen of 2 mice that had recovered from infection acquired about 45 and 93 days earlier; 112 other mice that were tested more than 5 weeks after recovery gave negative results. There was no evidence that such mice shed virus. However, because mouse tissues or tumours are passaged in other mice, such persistent infections, especially if they occurred in animals that had just recovered from a mild or inapparent infection, could constitute a source for the dissemination of mousepox (see *Laboratory animal science*, 1981).

A more significant observation in relation to possible persistent infection with orthopoxviruses was that recorded by Gledhill (1962a,b), who demonstrated that mice infected by the oral route could sustain a chronic infection of the intestinal tract, with excretion of virus in the faeces and scabs on the tail near the anus. He was unable to "activate" acute mousepox in such carriers, nor did they cause infection in susceptible mice placed in the same cages.

#### *Isolation of other orthopoxviruses from naturally infected normal animals*

A number of reports of the recovery of orthopoxviruses from the tissues of apparently normal animals have been published (Table 3.3). There are two problems in evaluating the significance of these findings, in terms of persistent infection. First, it is

Table 3.3. Recovery of orthopoxviruses from tissues of healthy animals thought to have been naturally infected<sup>a</sup>

possible that most or all of the positive results were obtained with animals that were experiencing an inapparent infection at the time or were convalescing from infection (examples 1(i), 1(ii), 2, 3 and 4 of Table 3.3). Secondly, the virus apparently isolated from a normal animal may have been a laboratory contaminant (examples 5(i) and 5(ii) of Table 3.3).

#### *Isolation of orthopoxviruses from "normal" animals after recovery from experimental infection*

Although most investigators have failed to demonstrate persistent infection with ortho-

poxviruses, there are several reports of the recovery of orthopoxviruses from the tissues of laboratory animals that had been infected several weeks earlier and were apparently normal at the time of isolation of the viruses (Table 3.4). The results with mousepox have been described. The most systematic studies were those reported by Marennikova and her colleagues with monkeypox and cowpox viruses (examples 2-5 of Table 3.4). The animals suffered inapparent infections and the relevant virus was recovered from some animals for up to 6 weeks after inoculation, when the experiment was terminated. Great

gerbils and yellow susliks suffered severe disease with high mortality after inoculation with the Turkmenia strain of cowpox virus, but virus could be recovered from the kidneys and testes of animals that survived for 5 weeks (example 5, Table 3.4).

Positive results were also reported with vaccinia virus in rabbits and mice (examples 6 and 7, Table 3.4) and variola virus in mice (example 8, Table 3.4).

### Epidemiological Significance

It is difficult to assess the epidemiological significance of these observations. Only in Gledhill's experiments with ectromelia was there any evidence that virus shedding occurred, but even then the infection of susceptible contact mice was not observed (Gledhill, 1962a,b). In all other cases the virus was in a sequestered site and its presence was revealed only by laboratory manipulations. It is reasonable to suggest that the persistent carriage and shedding of virus is not a factor of epidemiological significance in orthopoxvirus infections in the way that is so important in arenavirus and herpesvirus infections.

With smallpox, there is a further epidemiological observation of great significance. Over a period of some 50 years, during this century, smallpox was progressively eliminated from every country in the world. In no instance was a "spontaneous" outbreak identified after smallpox had been eliminated from a region or country. All outbreaks of which the source was found could be traced to the introduction of virus from known infected areas by known infected individuals.

These results are also relevant to the searches for the natural reservoir animal or animals of monkeypox in Africa (see Chapter 29) and the claims that variola virus has been isolated from various healthy primates and rodents (see Chapter 30). It is clear that orthopoxviruses have only very rarely been recovered from wild animals, even when tests were carried out in areas and with species in which there was serological evidence that orthopoxvirus infection was widespread. It is likely that virus isolation in such circumstances usually depends on the chance selection of an animal suffering or convalescing from infection rather than a long-term carrier. This appears to have happened with rodent strains of cowpox virus (examples 1(i) and 1(ii) of Table 3.3). The chance of catching

such an animal during an ecological survey in tropical forest areas, with their abundance and diversity of animals, is quite small, which may account for the failure so far to recover monkeypox virus from a wild animal (except in one instance from a sick squirrel), and in part for the rarity of cases of human monkeypox.

### THE IMMUNE RESPONSE IN SMALLPOX AND AFTER VACCINATION

Variolation, the ancient practice whereby smallpox was transmitted to a susceptible person by the inoculation of material from smallpox scabs or vesicles, was based on observations that pockmarked persons never suffered from smallpox a second time. It provided the foundation on which the science of immunology was built (Needham, 1980). The next major landmark in immunology, as Pasteur (1881) recognized when he generalized the use of the term vaccination, was Jenner's substitution of an antigenically related non-virulent agent (cowpox/vaccinia virus) for the virus of smallpox.

Although immunology arose from observations of protection from infection or reinfection, the immune response also plays an important role in the process of recovery in an infected person. In the following pages both aspects are reviewed.

#### Protection against Reinfection

##### *After vaccination*

The responses obtained on revaccination with vaccinia virus at various intervals after primary vaccination or earlier revaccination are described in Chapter 7. Immunity may be manifested by a complete absence of reactivity, by an allergic reaction or by an accelerated reaction which may nevertheless progress to vesiculation and which involves at least local replication of the virus used for revaccination. Skin site appears to play a role in the severity of the response to revaccination. In India revaccination was often performed on the ventral surface of the forearm because positive reactions were more frequently obtained there than in revaccination over the deltoid muscle. Even more striking were the finger lesions sustained by workers in vaccine production laboratories, who often

### Cells Involved in the Immune Response

The immune response is a complicated process about which a great deal has been discovered since most of the work on immunological responses in smallpox and vaccinia was carried out. Understanding of cell-mediated immunity, in particular, has burgeoned in recent years. A summary of current views on the cells involved in the immune response as they relate to viral infections is shown in Fig. 3.4.

Very briefly, three types of cell are involved - macrophages and two types of lymphocyte. Certain kinds of macrophage process antigens for presentation to lymphocytes. Lymphocytes belong to two main classes: T cells (meaning thymus-derived cells, of which there are several subclasses), and B cells (coming mainly from the bone marrow in mammals), which produce antibodies. B cells have antibody-like receptors on their surfaces, one or a few cells having receptors of every imaginable specificity. When an antigen is appropriately presented to such a cell by a macrophage, the B cell differentiates to form an antibody-synthesizing plasma cell and at the same time divides to form a population (clone) of identical cells. Later, some members of this clone are sequestered as long-lived memory B cells, which are of critical importance in mounting a secondary response when reinfection occurs.

T cells have different kinds of antibody-like receptors on their surface, and they also react specifically to different antigens, expand clonally, liberate active substances called lymphokines, and sequester a small proportion of each clone as long-lived memory T cells. There are several subclasses of T cells. Two of these modulate the activity of the antibody-producing B cells and of other T cells: Th or helper T cells and Ts or suppressor T cells. Other kinds of T cells are responsible for the two main components of the cell-mediated immune response: Tc or cytotoxic T cells, which actively destroy cells bearing complementary virus-induced antigens on their surface, and Td cells, which differentiate on contact with the specific antigen, release lymphokines and produce delayed hypersensitivity reactions. T cells also produce one class of interferon (gamma-interferon), and there is another poorly understood class of lymphocytes (natural killer (NK) cells), which appear to kill certain host cells non-specifically.

suffered from vaccinia whitlows in spite of the fact that they were revaccinated annually (Horgan & Haseeb, 1944). Such cases often exhibited enlargement of the epitrochlear and axillary lymph nodes and sometimes the reinfection progressed like a primary vaccinia reaction, with maximum vesiculation on the 9th or 10th day.

#### *After smallpox*

It is obviously difficult to obtain precise figures on the incidence of second attacks of smallpox. Dixon (1962), quoting from the observations of Barry (1889) in Sheffield, and Rao (1972), whose views were based on his own experience supported by laboratory evidence, suggested that about 1 in 1000 pockmarked persons suffered a second attack of smallpox. Epidemiologists working in the field during the Intensified Smallpox Eradication Programme believed that this figure

was rather high. Although collectively they saw many thousands of cases of variola major, it was very rare indeed to find one in a pockmarked person.

#### *Heterologous protection*

Depending on the closeness of the antigenic relationship and the degree of generalization of the infection (and thus the intensity of the immune response), homologous protection would be expected to be greater than protection induced by a heterologous agent. Experiments in animals reveal that infection with any one orthopoxvirus produces substantial protection against disease produced by any other orthopoxvirus (vaccinia virus against ectromelia in mice: Fenner, 1947a; ectromelia virus against rabbitpox in rabbits: Christensen et al., 1967; vaccinia virus against monkeypox in monkeys: McConnell et al., 1964; vaccinia virus against cowpox in rab-

Fig. 3.4. Cells involved in antiviral immune response. Tc = cytotoxic T cell; Td = delayed hypersensitivity T cell; K cell = killer cell; NK cell = natural killer cell.

bits: Downie, 1939b; vaccinia virus against variola in monkeys: Horgan & Haseeb, 1939; taterapox virus against monkeypox in monkeys: Lourie et al., 1975). Likewise, a prior attack of smallpox gave some protection against vaccination with vaccinia virus, which was much less prolonged after variola minor than after variola major (see Chapter 1, Table 1.10). Persons with active variola major, vaccinated in order to prevent smallpox infection in case of a misdiagnosis, never exhibited a major reaction (Zikmund et al., 1978).

However, the classic example of cross-protection, on which the success of the global eradication campaign depended, was that described by Jenner (1798). Although Jenner realized that cowpox inoculation did not always result in a take (Jenner, 1799, 1804), he maintained that successful vaccination produced lifelong immunity to smallpox. That view was clearly wrong, and revaccination became an accepted practice early in the 19th century in continental Europe, although it

was not widely practised until much later in Great Britain. Detailed information on the persistence of immunity to smallpox after vaccination with vaccinia virus is presented in Chapters 1 and 7. In general, vaccination within the previous 5 years protected persons exposed to smallpox against clinical disease and some protection was evident for over 30 years. In countries in which smallpox was endemic, estimation of the duration of protection was complicated by the fact that subclinical smallpox, recognizable by rises in the titre of complement-fixing antibodies (which persist for only a few months after infection), occurred in a substantial number of vaccinated individuals who were in close contact with cases of smallpox (Heiner et al., 1971a; see Chapter 1).

#### Humoral and Cellular Responses in Orthopoxvirus Infections

In orthopoxvirus infections the humoral response may result in the production of short-lived IgM or persistent IgG, and it may

be elicited by inactive virions or viral antigens and by both non-enveloped and enveloped infectious virions. The cellular response also may be evoked either by inactive antigens (which result in delayed hypersensitivity reactions without cytotoxic effects) or by cell surface membranes altered by viral infection, when both cytotoxic responses and delayed hypersensitivity may be involved.

In the analysis of the scientific literature which follows, the humoral and cellular immune responses will be discussed separately; however, in any animal inoculated or infected with viral antigens or virus preparations, the reactions described, and many others, go on simultaneously. In each section technical methods will be described first and then the results of experiments on orthopoxvirus infections in laboratory animals and on smallpox and vaccinia in man will be reported.

### Methods for Measuring Antibodies to Orthopoxviruses

At various times almost every method that has been developed for detecting antibodies has been employed for titrating antibodies to orthopoxviruses, especially in the case of vaccinia virus, the prototype virus of the genus. In the following paragraphs the methods more commonly used are listed, with comments about particular features of each, notably its sensitivity, the persistence of the antibodies detected by particular tests, the potential of the test for distinguishing between different species of orthopoxvirus, and the relation of antibodies detected by various tests to protection.

With the discovery of monoclonal antibodies and the subsequent development of this new tool, serological methods achieved a quantum leap in their power to detect and discriminate between antigenic sites (epitopes). In principle, monoclonal antibodies can be used to titrate either antigens, by any of the methods outlined below, or antibodies, by using them in blocking tests. At the time this chapter was written no use had been made of monoclonal antibodies in orthopoxvirus research.

#### *Sensitivity and specificity of different serological tests*

Different serological tests differ considerably in both sensitivity—i.e., the amount of antibody required to give a positive result—and specificity—i.e., their ability to discrimi-

nate between different but related antigens. Although they can be refined, if used with monoclonal antibodies or with antibodies produced by immunization with purified antigens, the first four tests described below ordinarily register reactions between several or all of the large number of antigens produced in orthopoxvirus infections and certain classes of all the antibodies, of varying specificity, that are produced during immunization or infection. Other serological tests are more discriminative, in that they involve only one or a few of the antigens produced during viral infection and the corresponding antibodies, or else the mixed antigen-antibody complexes can be separated by diffusion or electrophoresis in gels.

#### *Complement-fixation (CF) test*

Many poxvirus antigens react in CF tests, including an early antigen located on the surface of vaccinia-infected cells (Ueda et al., 1972). However, only antibodies of certain classes and subclasses (in man: IgM and to a lesser extent IgG<sub>1</sub>, IgG<sub>2</sub> and IgG<sub>3</sub>) participate in CF reactions; in general, such antibodies are short-lived so that a positive CF reaction is an index of recent infection (in man, within 12 months; Wulff et al., 1969). This property was exploited by Heiner et al. (1971a) in their study of subclinical infections in vaccinated household contacts of smallpox cases (see Chapter 1, Fig. 1.2).

Because so many antigens are common to all orthopoxviruses, the CF reaction is useless for discriminating between different species of the genus, unless used with an antigen that is species-specific.

#### *Immunofluorescence test*

Like the CF test, immunofluorescence can be used to detect many different orthopoxvirus antigens. However, in contrast to the antibodies active in complement fixation, the IgG antibodies involved in immunofluorescence reactions are long-lived (Gispen et al., 1974). Combined with serial absorptions of antisera with suitable suspensions of virus-infected tissue, immunofluorescence can be used to recognize species-specific orthopoxvirus antibodies in sera of animals caught in the wild (Gispen et al., 1976). However, it suffers from the disadvantage of being relatively insensitive. Immunofluorescence has proved useful in the study of the sequence of intracellular events in orthopoxvirus infec-

tions (Ueda et al., 1972) and in studies of the pathogenesis of poxvirus infections in experimental animals (Mims, 1964, 1966), for it provides a method of demonstrating the cellular and intracellular localization of viral antigens.

#### *Radioimmunoassay*

The sensitivity of several serological methods can be greatly enhanced by tagging relevant antigens or antibodies with radioisotopes. Radioimmunoassay, which is about a thousand times more sensitive than immunofluorescence, for example, can be used for the detection of antigen antibody reactions in tubes or plates, or it can be combined with gel precipitation and autoradiography to discriminate between antigens produced in orthopoxvirus infections (radioimmunoprecipitation, see below).

Hutchinson et al. (1977) developed a radioimmunoassay test for detecting species-specific orthopoxvirus antibodies in absorbed sera, which because of its sensitivity could be applied to sera obtained during field surveys.

#### *ELISA method*

Like the complement-fixation, immunofluorescence and radioimmunoassay tests, the ELISA (enzyme-linked immunosorbent assay) method provides a sensitive way of recognizing antigen-antibody reactions. It was developed rather too late to have been much used in research on smallpox and vaccination, but it constitutes a potentially useful field test for ecological studies of monkeypox, particularly if it can be used with a monkeypox-specific antigen or, in blocking tests, with suitable monoclonal antibodies.

#### *Neutralization test*

Neutralization of infectivity is the traditional discriminative test in animal virology, and is used to distinguish between different species of *Alphavirus* and *Flavivirus*, for example, or different strains of *Influenzavirus*. The antigens which evoke neutralizing antibodies after infection with orthopoxviruses, however, show a great deal of overlap (i.e., several epitopes are shared by all members of the genus), so that, as ordinarily performed, neutralization tests detect genus-specific rather than species-specific antibodies.

The neutralization of infectivity of orthopoxviruses can be carried out by testing virus-

serum mixtures in experimental animals (rabbit skin: Parker, 1939; mouse brain: Bronson & Parker, 1941), or by looking for plaque or focus reduction in cultured cells (McNeill, 1965; Kitamura & Shinjo, 1972) or pock reduction on the chorioallantoic membrane (Keogh, 1936; McCarthy et al., 1958a). All species of *Orthopoxvirus* cross-react in neutralization tests, although titres are highest with the homologous virus (Downie & McCarthy, 1950; McNeill, 1968). In man, neutralizing antibody persists for many years after recovery from both smallpox and vaccination with vaccinia virus (McCarthy et al., 1958a,b; Downie & McCarthy, 1958).

Traditionally, neutralization tests have been carried out with suspensions of virions obtained by disrupting infected cells. Since such virions lack the envelope antigens found in naturally released virions (see Chapter 2), these neutralization tests do not measure all the antibodies that are important in protecting against infection or acting against circulating virions. Antibodies that neutralize the infectivity of enveloped virions can be assayed by the "anti-comet" test of Appleyard et al. (1971) (Plate 3.10). In essence, this test involves the use of a liquid overlay for cell monolayers infected with suitable concentrations of a strain of an orthopoxvirus, such as rabbitpox virus, that produces many enveloped virions. These migrate in the liquid overlay to produce comet-shaped areas of cell damage. Antibodies that neutralize the infectivity of envelope antigens, added after viral adsorption, prevent the formation of the "comets" but not the development of plaques. Antibodies to non-enveloped virions have no such effect, but prevent plaque production in orthodox neutralization tests, in which virus-serum mixtures are added to the monolayer.

#### *Haemagglutination-inhibition (HI) test*

All orthopoxviruses, but no other members of the family *Poxviridae*, produce a haemagglutinin which agglutinates cells from selected chickens. Because of its simplicity, the HI test has been widely used in serological surveys in man and in animals (e.g., for elucidating the ecology of monkeypox virus, see Chapter 29). The haemagglutinin appears early in the course of infection as one of several new components of the surface membrane of infected cells (Blackman & Bubel, 1972), where it may be recognized by haemadsorption tests (Driessen & Greenham, 1959).

**Plate 3.10.** The "anti-comet" test. Strains of virus which produce substantial numbers of extracellular enveloped virions produce "comet tails" from the initial plaques when suitable dilutions are inoculated in monolayers with a liquid overlay medium (A). Addition to the overlay medium of antibody to viral envelopes or enveloped virions, or of antiserum from an animal that has been infected with vaccinia virus, prevents the production of the "comet tails" but not of the initial plaques (B). Antiserum to surface tubular elements or inactivated virions, although it neutralizes the infectivity of non-enveloped virions, does not inhibit "comet" formation. (From Appleyard et al., 1971.)

Haemadsorption tests are useful in confirming whether suspicious cytopathic effects in tissue culture are caused by an orthopoxvirus. The haemagglutinin also occurs as a component of the viral envelope (Payne & Norrby, 1976), but separately from infectious non-enveloped virions in extracts of infected cells. Haemagglutinins produced by different orthopoxviruses cross-react, although titres are usually higher with the homologous virus.

According to Downie and his colleagues (McCarthy et al., 1958b; Downie & McCarthy, 1958), antibodies with HI activity persist for varying periods after recovery from orthopoxvirus infection, usually for only a few months but somewhat longer than CF antibodies (see Fig. 3.6 and 3.7). Thus they were useful in determining whether recent infection with smallpox had occurred and were so used by Heiner et al. (1971a), but have limitations when used for epidemiological or ecological surveys aimed at determining the prevalence of orthopoxvirus infections. However, using a somewhat different protocol for the preparation of vaccinia haemagglutinin, Nakano (1985) found that HI antibodies were more persistent than previously thought. In tests on African subjects who had recovered from monkeypox, he found positive results in some individuals more than 4 years after recovery. Further, when sera from 600 Africans of all

ages were tested for HI and neutralizing antibodies, more than 60% gave positive results by one or the other test. Most of these were positive by both tests but some gave positive results by HI but not by neutralization, and vice versa.

Non-specific inhibitors of orthopoxvirus haemagglutinin occur in some sera, especially if the specimens are old, have been improperly stored or were collected during autopsy. They can usually be removed from human sera without loss of specific antibody by treatment with potassium iodate (Espmark & Magnusson, 1964).

Some strains and mutants of orthopoxviruses fail to produce a haemagglutinin or to promote the production of HI antibodies (Cassel, 1957; Fenner, 1958). Experiments with these viruses, and other evidence, show that HI antibodies are unrelated to those involved in neutralization reactions, or to protection against infection, although the presence of HI antibodies is evidence that the antigens that do evoke the production of protective antibodies have been produced.

#### *Precipitation tests*

Much of the early work on the soluble antigens produced in orthopoxvirus-infected cells, involving both the time course of their

production (e.g., Appleyard & Westwood, 1964a) and comparisons between strains and mutants of orthopoxviruses (e.g., Gispén, 1955; Randle & Dumbell, 1962), utilized simple gel-precipitation tests. With the use of absorbed sera, reactions can be detected which differentiate variola, monkeypox and vaccinia viruses (Gispén & Brand-Saathof, 1974; Esposito et al., 1977a). However, the sensitivity of simple gel-precipitation tests is low; they require highly potent sera and are not readily applicable to sera obtained from animals that have recovered from natural infections.

Gel precipitation used to be recommended as a method for rapid smallpox diagnosis, using vaccinia-immune sera and vesicle fluid or crust material as a source of antigen (World Health Organization, 1969a; see Chapter 2). It was widely used for rapid presumptive diagnosis in laboratories which lacked facilities for electron microscopic diagnosis (Rao, 1972; A.W. Downie, personal communication, 1981), but was rarely employed in WHO collaborating centres after electron microscopy by negative staining had been developed. Further, although it was almost always positive with fresh material (Noble et al., 1970), its efficiency was much lower (only about 70%) in material that had been dispatched from the field to a WHO collaborating centre (see Chapter 2, Table 2.10).

The sensitivity and discriminative power of gel precipitation were greatly enhanced by two modifications: (1) electrophoresis of the viral antigens or antigen-antibody complexes in SDS-polyacrylamide gels, and (2) radioisotopic labelling of the antigens. The radio-immunoprecipitation test was used by Ikuta et al. (1979) to demonstrate the presence of serologically related antigens among poxviruses of the same and different genera.

### The Humoral Response in Relation to Pathogenesis

Until comparatively recently, the "immune response" was equated with the production of antibodies. It is now clear that cell-mediated immunity is of even greater importance than antibodies in the pathogenesis of many infectious diseases, and in every infected animal or human being with a normal immune system humoral and cellular immunity always operate simultaneously. It is convenient, however, to consider these two aspects of the immune response separately.

During infection with a virus as complex as an orthopoxvirus, antibodies of many different specificities are generated. Most of these are probably irrelevant, as far as the pathogenesis of poxvirus infections, recovery and protection are concerned. The relevant antibodies belong to three classes: (1) antibodies that neutralize viral infectivity, of which there are two subclasses, directed respectively against non-enveloped and enveloped virions (review: Boulter & Appleyard, 1973); (2) those that, with complement, lyse virus-infected cells (review: Sissons & Oldstone, 1980); and (3) antibodies that combine with circulating antigens to produce immune complexes, which might have been responsible for some of the "toxic" symptoms in smallpox.

It has long been believed that specific antibodies generated by the humoral immune response played important roles in both protection against orthopoxvirus infections and recovery from established infections. The protective effect of antibodies is most clearly demonstrated by passive immunization; their putative role in recovery was based mainly on temporal relationships observed during the course of established infections.

#### *Passive immunity*

Passive immunization, either natural, by the transmission of antibodies from mother to progeny, or by the inoculation of antiserum, provides a means of examining the influence of antibodies on the disease process uncomplicated by cell-mediated immunity. The effect of passive immunization in protecting against infection with vaccinia virus was recognized as long ago as 1877 (Raynaud, 1877). The effectiveness and the limitations of passive immunization in generalized poxvirus infections are well illustrated in experiments on mousepox (Fig. 3.5). Active immunization with ectromelia virus (not illustrated) usually inhibited viral replication in the inoculated foot and always prevented generalization of the disease. Active immunization with vaccinia virus (Fig. 3.5B) had little effect on viral replication in the foot but greatly diminished generalization, although a transient rash sometimes occurred. The antibody titre rose and the relative titres against ectromelia and vaccinia haemagglutinins were reversed between 7 and 8 days after infection. Passive immunization was much less effective in modifying the course of the disease. Vaccinia-immune serum (Fig. 3.5D)

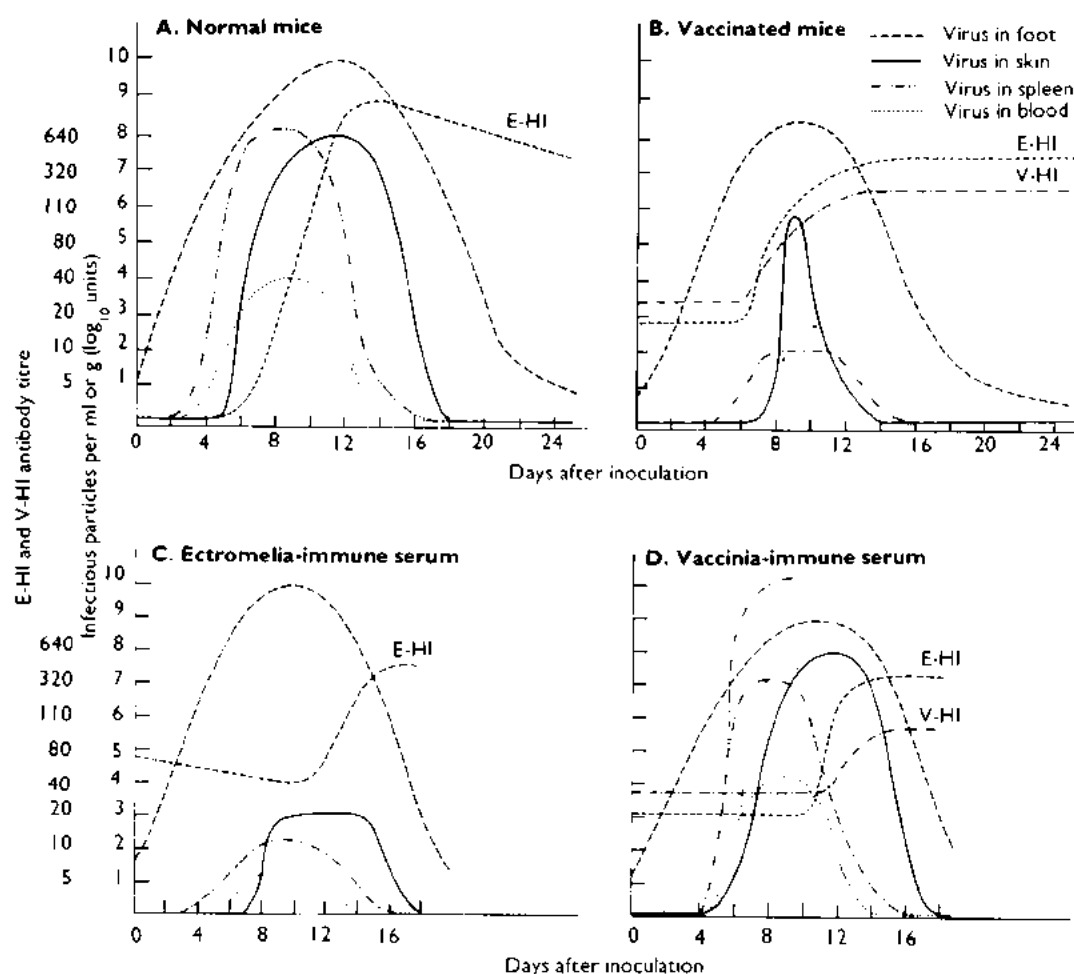

Fig. 3.5. The spread of ectromelia virus through the organs of mice, either unprotected (A), or protected by active immunization with vaccinia virus (B), or by passive immunization with ectromelia-immune serum (C) or vaccinia-immune serum (D) obtained from convalescent mice. E-HI and V-HI = haemagglutinin-inhibiting antibodies to ectromelia (E) and vaccinia (V) antigens. (From Fenner, 1949b.)

had almost no effect and several mice died with acute hepatitis at the same time as the controls. Ectromelia-immune serum (Fig. 3.5C) was more effective but did not influence viral replication in the inoculated foot, and a low level of replication in the spleen and skin was found in most animals. In passively immunized mice the antibody level rose about 2 days later than it did in the vaccinated mice.

These experiments illustrate two important features of passive immunization that are relevant to vaccination and smallpox in man. First, active immunization, whether heterologous (by vaccination) or homologous (after recovery from mousepox and, by analogy, from smallpox), provided much greater protection than the administration of pre-

formed antibodies, even when the antibody titres in the passively immunized mice were higher than those in the actively immunized animals. The reason for the difference is that active immunization with infectious virus provokes the complete range of cell-mediated and humoral immune responses; passive immunization provides only the antibodies present in the convalescent animals from which the sera were obtained. Secondly, passive immunization with the homologous antibody provided much greater protection than did heterologous antibody, even though the sera cross-reacted extensively in neutralization tests. In relating these experiments to human vaccination and infection with variola virus it is important to realize that vaccinia and

variola viruses cross-react to a greater degree than do vaccinia and ectromelia viruses.

Experiments on passive immunization in rabbitpox (Boulter et al., 1961b) confirmed the protective value of potent homologous antiserum, which protected rabbits from death, even when treatment was delayed until overt disease had developed. Subsequent experiments (Boulter et al., 1971; see Table 3.5) showed that antisera produced after infection with live virus had a much greater protective effect than antiserum produced by immunization with inactivated virus, even when the neutralizing titre, measured by orthodox neutralization tests, was much lower.

Thus antibodies as such do have an effect on viral replication and spread in generalized poxvirus infections, although, as described below, cell-mediated immunity is probably more important. The influence of congenital passive immunization and the administration of antisera to smallpox cases or contacts is discussed in Chapter 1; the use of anti-vaccinia gamma-globulin in generalized vaccinia is dealt with in Chapter 7.

#### *The antibody response during infections*

In almost every kind of viral infection that has been studied, there is a relationship between the time at which circulating neutralizing antibodies first become detectable and the progressive decrease and eventual disappearance of virus in the blood and parenchymal tissues. However, the simultaneous activation of cell-mediated immunity and the possible earlier effects of interferon production (see below) make interpretation difficult.

#### *Neutralizing antibodies and protective immunity*

From the point of view of protection against natural infection, the antibody that neutralizes enveloped virions is theoretically more important than the antibody that neutralizes non-enveloped virions (review: Boulter & Appleyard, 1973). However, almost all reported studies of the role of neutralizing antibodies in the pathogenesis of poxvirus infections were carried out before the demonstration of the significance of enveloped virions, and assays of neutralizing antibodies have been performed with virus suspensions obtained by disrupting infected cells, and thus have measured antibody to non-enveloped virions. It is likely that relatively few virions

circulate in this form during poxvirus infections; they are either cell-associated, in cells whose surface membranes may be altered by the incorporation of virus-specific antigens, some of which are similar to those found on the viral envelope, or they occur outside cells (in plasma or tissue fluids) as enveloped particles.

Antibody which specifically neutralizes enveloped virions can be detected by the "anti-comet" test (see Plate 3.10). The differences between neutralizing antibodies to enveloped and non-enveloped virions are particularly important in relation to efforts to produce inactivated vaccines for protection against smallpox (see below). The relevant features of the experiments by Boulter, Appleyard and their colleagues (Appleyard et al., 1971; Boulter et al., 1971; Turner & Squires, 1971) and later experiments by Payne (1980) can be summarized as follows:

(1) Sera of rabbits which had recovered from infection with rabbitpox virus contained antibodies that neutralized enveloped virions; sera from rabbits inoculated with inactivated virions lacked such antibodies.

(2) Sera from both groups of rabbits neutralized non-enveloped virions.

(3) Cross-absorption of the two types of sera with concentrated enveloped or non-enveloped virions selectively removed neutralizing antibodies of the appropriate specificity.

(4) Antibody to isolated envelopes was able to neutralize the infectivity of enveloped virions and to protect mice against the spread of infection.

(5) Rabbits immunized with inactivated rabbitpox virus (i.e., with inactivated non-enveloped virions) had high levels of neutralizing antibodies to non-enveloped and none to enveloped virions, but showed only partial immunity on challenge inoculation, whereas rabbits immunized with enveloped virions were fully protected.

#### *Antibody-mediated complement-dependent lysis*

Oldstone and his collaborators (reviews: Oldstone & Lampert, 1979; Sissons & Oldstone, 1980) have shown that antibodies can exert a number of significant effects on virus-infected cells. In conjunction with complement or cytotoxic lymphocytes, IgG antibody can mediate the destruction of virus-infected cells. In experiments with vaccinia in humans,

Perrin et al. (1977) suggested that lysis of virus-infected cells was more likely to be due to non-specific "killer" lymphocytes (NK cells) acting in the presence of antibody to viral antigens located in the cell membrane than to specifically sensitized cytotoxic lymphocytes.

#### *Immune complexes as a cause of toxæmia*

Soluble orthopoxvirus antigens and immune complexes could be readily demonstrated in the plasma of severe cases of smallpox (Downie et al., 1953). It is possible that these immune complexes played a part in the production of the toxæmia that was so characteristic of variola major.

### **Methods for Measuring Cell-Mediated Immunity**

#### *Nature of the cells involved*

Although observers had long been concerned with the frequent lack of correlation between circulating antibodies and recovery from infections, "cellular immunity", invoked in such situations to explain recovery from disease, had no precise meaning until the complex immunospecific responses of T cells were recognized during the 1970s, distinct and independent of the antibody-producing B cells. The T-cell responses, other than those involved in modulation of the humoral response (see Fig. 3.4), constitute cell-mediated immunity. The mechanisms by which T lymphocytes exercise antiviral functions are complex; they may involve both the direct effects of T cells on cells with virus-modified surface membranes and the effects of their secreted products, which are called lymphokines and include, among others, gamma-interferon.

#### *The delayed hypersensitivity reaction*

The classical method of measuring cell-mediated immune responses is the skin test for delayed hypersensitivity, an expression used to contrast the time course and nature of the reaction with that of "immediate" hypersensitivity, which comes on within minutes of exposure to the relevant antigen and is mediated by IgE (Gell et al., 1975). It is a complex reaction involving three components: (1) an initial one in which antigen-sensitive T cells are sensitized, a procedure

that may require the prior processing of antigens in macrophages; (2) a further component, consisting of antigen recognition and the proliferative response of T cells, with release of lymphokines; and finally (3) an inflammatory response which is amplified by chemotactic factors. Delayed hypersensitivity can be passively transferred by suspensions of lymphoid cells, but not by antiserum. Two subclasses of T cell may be involved in delayed hypersensitivity reactions (Fig. 3.4): (1) cytotoxic T cells (T<sub>c</sub>) are evoked by viral infection and have cytotoxic activity, reacting specifically with virus-induced antigens on cell membranes; (2) delayed hypersensitivity T cells (T<sub>d</sub>) are evoked by antigen presented in a non-multiplying form, such as inactivated vaccines, as well as during viral infections; these T cells are not cytotoxic (Ada et al., 1981).

Delayed hypersensitivity is recognized by the accelerated response to inoculation of the antigen(s) into the skin; its development during vaccine inoculation of man was recognized by Jenner (1798) and has been repeatedly demonstrated since then (e.g., Pincus & Flick, 1963). It was commonly used as a method of assessing immunity to smallpox, but its reliability for this purpose depended on which kind of T cells produced the reaction. If they were cytotoxic T cells produced by prior infection with active virus, delayed hypersensitivity was a good index of resistance. If they were the kind of T cell (T<sub>d</sub>) provoked by a non-multiplying antigen, which lacked cytotoxic capacity, there was usually no correlation between delayed hypersensitivity and resistance—i.e., delayed hypersensitivity is an indicator of resistance only when it is an indicator of the presence of cytotoxic T cells (Ada et al., 1981).

#### *In vitro techniques for analysing T-cell function*

There is no satisfactory *in vitro* assay of delayed hypersensitivity; the reaction involved is a particular kind of inflammatory response which must be tested in intact animals. However, in experimental systems there is a good assay for cytotoxic T cells. A known number of <sup>51</sup>Cr-labelled, virus-infected target cells are cultured together with varying numbers of lymphocytes obtained from the spleen or lymph nodes. The release of the radioactive label is an index of cytotoxic T-cell activity; proof that it is due to T cells is provided by the absence of lysis if the

lymphocyte preparation is treated with anti-theta serum and complement.

*In vitro* experiments with cells infected with ectromelia virus (Ada et al., 1976; Jackson et al., 1976) and with vaccinia virus (Koszinowski & Ertl, 1976) showed that some of the cell-surface changes relevant to T-cell-mediated lysis occurred before viral DNA replication had begun—i.e., they were “early” synthetic functions coded for by the input DNA.

The mechanism of cytotoxic T-cell lysis was shown by Zinkernagel & Althage (1977) to be a direct interaction between the appropriate T cells and cells infected with vaccinia virus. Recognition by T cells depended on the presence on the membranes of infected cells of both virus-specified antigens and the appropriate major histocompatibility gene products. The early lytic effect ensures that cells are lysed before progeny virions are assembled and thus accounts for the efficiency of cell-mediated immunity in the control of established infections with orthopoxviruses (see below).

### Cell-Mediated Immunity in Relation to Pathogenesis

There is even more need to make use of model systems in laboratory animals to elucidate the role of various components of the immune response in smallpox than in studies of the spread of infection during the incubation period. Mice are particularly suitable, since so many genetically defined mouse lines are available. Mousepox, which proved so useful for studying other aspects of pathogenesis, is the system most likely to provide clues as to the relative importance of humoral and cell-mediated immunity in smallpox, and has been extensively exploited for this purpose (Blanden, 1970, 1971a,b; reviews: Blanden, 1974; Cole & Blanden, 1982).

#### *Experiments with mousepox*

Mechanisms controlling viral growth in the major visceral target organs (liver and spleen) become operative 4–6 days after primary infection by the natural route, which in the experimental studies was simulated by subcutaneous inoculation into the footpad. Cell-mediated immune responses occur soon after infection: virus-specific cytotoxic T cells are detectable 4 days after infection and reach peak levels in the spleen 1–2 days later,

while delayed hypersensitivity is detectable by the footpad test 5–6 days after infection. In contrast, significant neutralizing antibody is not detectable in the circulation until the 8th day.

Mice pretreated with anti-thymocyte serum, which acts specifically on T lymphocytes, die from otherwise sublethal doses of virus, because of uncontrolled viral growth in target organs. Such mice have impaired cell-mediated responses but their neutralizing antibody levels are normal, interferon levels in the spleen are elevated, and the innate resistance in target organs is unchanged.

Very large doses of interferon or immune serum transferred to previously infected recipients are relatively ineffective against the established infection in target organs, although high levels of interferon and high antibody titres can be demonstrated in the sera of the recipients. On the other hand, immune spleen cells harvested 6 days after active immunization of the donor transfer specific and highly efficient antiviral mechanisms which rapidly eliminate infection from the target organs of the recipients, in whose serum neither antibody nor interferon is detectable. The active cells in the immune population can be identified as cytotoxic T cells. Mononuclear phagocytes of immune T-cell recipients, labelled with tritiated thymidine before T-cell transfer, appear in foci of infection in the liver after T-cell transfer, and prior irradiation of immune T-cell recipients in a regimen designed to reduce blood monocyte levels significantly reduces the antiviral efficiency of the transferred cells.

These findings support the idea that blood-borne cytotoxic T cells with immunological specificity for virus-induced antigenic changes in infected cell surface membranes enter infectious foci and retard viral spread by lysing infected cells before the maturation and assembly of progeny virions. This T-cell activity attracts blood monocytes which contribute to the elimination of infection by phagocytosis and intracellular destruction of virus. Macrophage activation and locally produced interferon may increase the efficiency of virus control and elimination, but are less important than T cells.

Recognition of the importance of cytotoxic T cells in controlling the replication of ectromelia virus in foci of infection does not mean that humoral antibodies do not also play a role in pathogenesis. Indeed, the early

experiments of Fenner (see Fig. 3.5) with convalescent antiserum from ectromelia-immune animals showed that antisera do have an effect on the progression of infection, probably in controlling the viraemia.

### The Immune Response in Smallpox

Because it is so easy to obtain serum, because many serological tests for antibodies are simple to perform, and because the development of knowledge about cell-mediated immunity is relatively recent, studies of the immune response in smallpox and after vaccination are dominated by reports on the humoral component of the immune response and very deficient in observations on cell-mediated immunity.

#### *Antibody production in cases of smallpox*

The most comprehensive studies on the serological responses to smallpox are those reported by Downie and his colleagues in 1958 and 1969. Working with variola major patients in Madras, India, Downie et al. (1969a,b) examined the sera of 151 patients with ordinary-type and modified-type smallpox, 37 patients with early haemorrhagic-type smallpox and 40 patients with late haemorrhagic-type smallpox.

In non-haemorrhagic smallpox haemagglutinin-inhibiting (HI) and neutralizing antibodies showed rising titres from the 6th day of illness (i.e., approximately 18 days after infection) and most patients developed antibodies demonstrable by gel precipitation or by complement fixation (CF) some 2 days later. Most of the patients studied were adults who had scars attributed to childhood vaccination; the antibody response usually occurred a few days later in unvaccinated than in vaccinated patients.

Most of the patients with haemorrhagic-type smallpox were adults with old vaccination scars (Rao, 1972). Their antibody responses were much lower, and occurred later, than those of patients suffering from ordinary-type or modified-type smallpox. Only 5 patients, all with late haemorrhagic-type smallpox, developed antibody that reacted in the precipitation test; 4 of these patients and 2 others were the only ones with CF antibody. Tests for HI antibody, on the other hand, were almost always positive and the titres were comparable to those found in non-haemorrhagic smallpox. The titres of neutral-

izing antibodies were much lower than those in non-haemorrhagic smallpox and the reaction was often still negative when the patient died. Cases of haemorrhagic-type smallpox, but not other types, always had high and sustained viraemia and antigenaemia (see Fig. 3.2).

Another important aspect of the humoral response was the persistence of antibodies after recovery from smallpox, as detected by different tests. Downie & McCarthy (1958) provide relevant data on some of the sera from 32 British cases of variola major (of whom 25 survived) and 19 cases of variola minor. The results (Fig. 3.6), expressed on several time frames and on a logarithmic time scale, showed that the levels of neutralizing and HI antibodies rose on about the 6th day of illness and the level of CF antibodies about 2 days later. Neutralizing antibody titres usually persisted for several years, HI titres usually fell to low levels by the 5th year after infection, and CF antibody titres rarely persisted for as long as 1 year.

#### *Cell-mediated immunity in smallpox*

Understanding of the importance of cell-mediated immunity in the recovery process in poxvirus infections came too recently for appropriate studies to have been conducted in cases of smallpox, although it would have been of considerable interest to see whether the T-cell responses were defective in flat-type and haemorrhagic-type smallpox. The extent of the rash precluded studies of delayed hypersensitivity by skin tests. The only report on cellular immunity in smallpox is that of Jackson et al. (1977), who determined the proportion of T and B cells in the peripheral blood of 17 smallpox patients in Bangladesh, at times varying between 3 and 21 days from the onset of illness. The T-cell counts were consistently lower in smallpox patients than in the controls; in 2 out of 4 fatal cases the B-cell counts were lower than in any of the controls. The 2 patients who had the highest null cell counts (lymphocytes not identified as either T or B cells) died, while 5 patients with consistently low null cell counts survived. Since no effort was made to determine the nature of the T cells studied, this result can only be regarded as preliminary. If it were possible to carry them out, studies on patients with human monkeypox would provide the only opportunity left to extend these investigations.

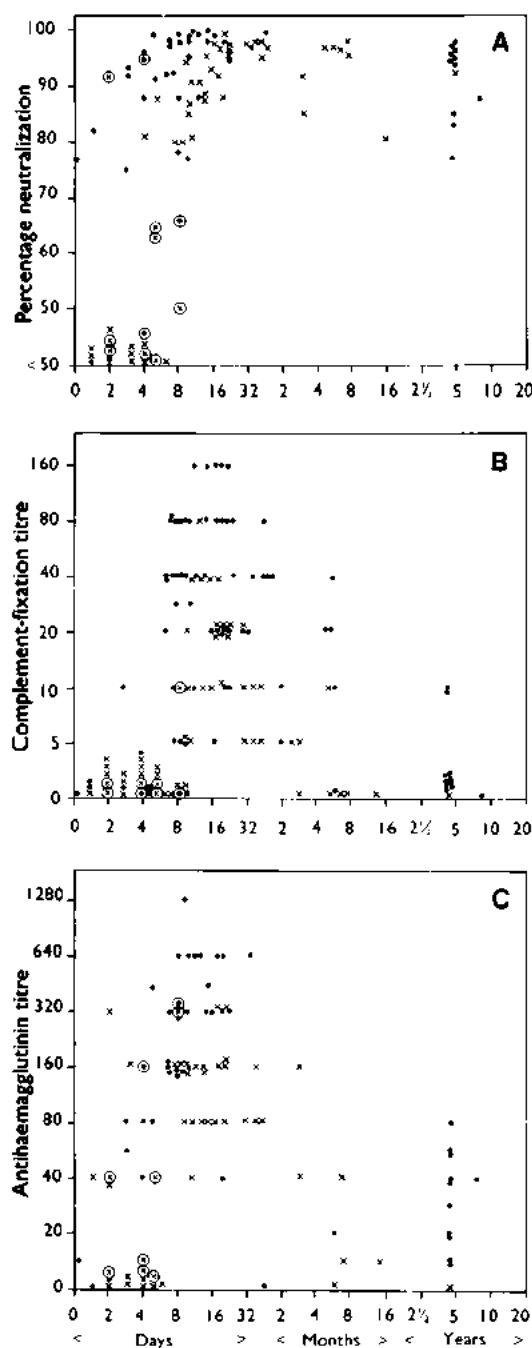

Fig. 3.6. Antibody production and persistence in cases of non-haemorrhagic smallpox (variola major and variola minor, not differentiated), as determined by various tests. **A:** Neutralization of variola virus pock production on the chorioallantoic membrane; **B:** Complement fixation with vaccinia antigens; **C:** Inhibition of haemagglutination by vaccinia haemagglutinin. Note that the abscissa has several time scales, all logarithmic, and that day zero corresponds to the onset of illness—i.e., about 12 days after infection. ● = vaccinated; × = unvaccinated; ⊗, ⊗ = fatal cases. (From Downie & McCarthy, 1958.)

## The Immune Response after Vaccination

There have been numerous studies of the immune response after vaccination, in both human subjects and laboratory animals, especially rabbits. Most have been concerned only with humoral antibodies and, when neutralizing antibodies were assayed, only with tests involving non-enveloped virions.

### *Antibody production after vaccination*

The results obtained by Downie and his colleagues in vaccinated and revaccinated human subjects (McCarthy et al., 1958b) provide comparability with the antibody responses in smallpox just described. Following primary vaccination, no antibody was detected up to the 10th day, after which neutralizing and HI antibodies were present in the majority of individuals and CF antibodies in less than half (Fig. 3.7). Neutralizing antibodies were clearly much the most persistent, sometimes being demonstrable for more than 20 years after primary vaccination. HI antibody was less persistent, and its persistence varied more markedly from subject to subject. CF antibody was not found more than 6 months after primary vaccination. In revaccinated individuals (several of whom possessed neutralizing antibodies before revaccination), the antibody titres tended to be higher, and when a response occurred, it began earlier, often within 7 days. In several revaccinated individuals CF and HI antibodies failed to appear even when there was a substantial rise in neutralizing antibody. It was noteworthy that only about half the revaccinated subjects who showed an "early" or "immediate" type of vaccination response developed neutralizing antibody.

When these results are compared with those recorded in Fig. 3.6 for non-haemorrhagic smallpox, it is clear that, calculated from the time of infection rather than the onset of disease, antibodies appeared more quickly after vaccination than in an attack of smallpox. The disparity was even greater in revaccinated subjects. This result, not unexpected in view of the much shorter incubation period and more rapidly progressive disease process in vaccinia (see Fig. 3.1 and Chapter 1, Fig. 1.3), explains why primary vaccination, given early after exposure, often modified and sometimes aborted an overt attack of smallpox. The appearance of neutralizing antibodies after vaccination with live virus is an

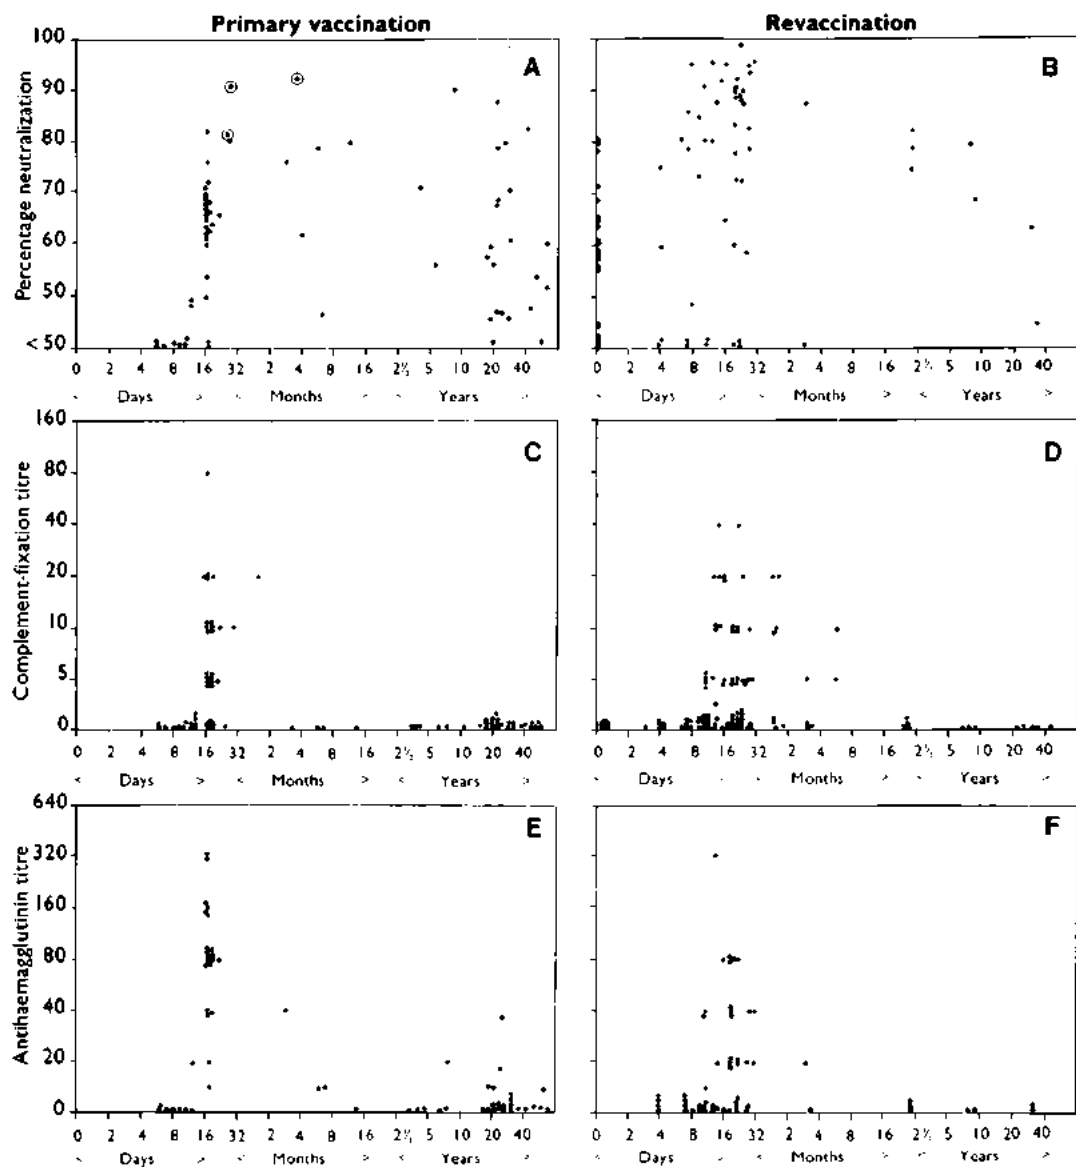

Fig. 3.7. Antibody production and persistence after primary vaccination (panel on left: **A, C, E**) and revaccination (panel on right: **B, D, F**), as determined by various tests. **A** and **B**: Neutralization of variola virus pock production on the chorioallantoic membrane; **C** and **D**: Complement fixation with vaccinia antigens; **E** and **F**: Haemagglutination inhibition of vaccinia haemagglutinin. Note that the abscissa has several time scales, all logarithmic, and that day zero corresponds to the day of infection with vaccinia virus. Circled dots in **A** represent cases of generalized vaccinia. (From McCarthy et al., 1958b.)

index of an active immune response which would include the development of antibodies to all viral antigens, as well as increased cell-mediated immunity. The accelerated immune response in revaccination (within a week, compared with over 10 days in primary vaccination) was of considerable importance in protecting persons by vaccination after exposure to smallpox.

#### *Cell-mediated immunity after vaccination*

Pincus & Flick (1963) demonstrated that delayed hypersensitivity, which is one index of cell-mediated immunity, developed rapidly after vaccination; they suggested that it played an important role in the pathogenesis of vaccinia lesions, both after primary vaccination and after revaccination. By vaccinating children twice, at intervals of 2 days,

they showed that the incubation periods for the 2nd vaccination, with regard to both papule and vesicle, were greatly shortened.

A delayed hypersensitivity response can be elicited in vaccinated subjects by either killed or active vaccine (Benenson, 1950), so that an "immediate" reaction to revaccination (reaching its maximum within 72 hours) does not necessarily mean that the subject's immunity has been boosted by reinfection. Nevertheless, it indicates that he possesses some residual allergy. If a potent live vaccine is used, with a satisfactory technique, this may be the only reaction seen in highly immune subjects. In those in whom immunity has waned somewhat this allergic response is followed by an enlarging area of erythema, often with vesiculation in the centre, which becomes maximal earlier than in a primary vaccination. The absence of such erythema by the 3rd or 4th day after primary vaccination is indicative of a deficient cell-mediated immune response and such patients may suffer from progressive vaccinia (see below).

#### *Immunological deficiency states in man*

The effects of immunological deficiency states in human subjects who had been vaccinated with vaccinia virus provides the best available information on the relative importance of cell-mediated and humoral responses in determining recovery in orthopoxvirus infections in man. Fulginiti et al. (1968) described a number of cases of progressive vaccinia (vaccinia necrosum) in such infants and children, and Kempe (1980) has summarized his extensive experience with these conditions, in relation to vaccination. In children with immunological defects in cell-mediated immunity, vaccinia virus replicated without restriction, resulting in a continually progressive primary lesion (see Chapter 7, Plate 7.8B), persistent viraemia and widespread secondary viral infection of many organs, including the skin. This response was particularly severe in patients with thymic aplasia. In patients with thymic dysplasia and partially or completely intact immunoglobulin-synthesizing capacity (Nezelof's syndrome) the progression of the primary disease was sometimes slower and less persistent, but a fatal outcome was usual (Kumar et al., 1977).

Fig. 3.8 sets out various kinds of immunological defect schematically and suggests the kinds of response that occurred when such

individuals were vaccinated. Cell-mediated immunity was clearly of major importance in controlling vaccinia infection, since individuals with defects in cell-mediated immunity but intact antibody production (Categories 3 and 5, Fig. 3.8) suffered from progressive vaccinia, while those with defects in antibody production but a satisfactory capacity to mount a cell-mediated immune response (Category 4) usually reacted normally to vaccination. Freed et al. (1972) suggested that in some circumstances, especially when the immunological defect was acquired (Category 6), the administration of vaccinia-immune globulin (VIG) would allow cell-mediated immunity to recover sufficiently to control the vaccinia infection. Also, in some cases of Bruton's syndrome a partially deficient cell-mediated immune mechanism might have been "overwhelmed", but could be restored to effectiveness by the administration of vaccinia-immune globulin.

Delayed hypersensitivity reactions could never be evoked in patients with progressive vaccinia, nor could the peripheral blood lymphocytes of such patients be stimulated to mitosis by exposure to inactivated vaccinia virus (Fulginiti et al., 1968). Although neutralizing antibody was sometimes present in the serum, its presence did not prevent the development of progressive vaccinia if cell-mediated immunity was defective (Hansson et al., 1966). Kempe (1980) records having seen 15 boys with very low levels of gamma-globulin, who had been routinely vaccinated in infancy without complications. All had histories of "enormous and hyperactive" delayed hypersensitivity responses to vaccinia antigens.

#### **Cells Involved in Immunological Memory**

By far the most important aspect of vaccination against smallpox was the fact that the vaccinated individual was primed, so that he responded more quickly and effectively than an unvaccinated person to infection with the antigenically related variola virus. Orthopoxvirus-specific T-cell and B-cell memory can be envisaged as comprising previously induced lymphocytes, of both T and B classes and all subclasses, which persist as non-functioning long-lived cells in lymphoid tissues and the recirculating pool of lymphocytes. In the spleens of mice infected with ectromelia virus, the appearance of memory T

Immunological condition	Immunological status	Response to vaccination
1. Normal, vaccinated	(+)CMI+; (+)Ab+	CMI+; Ab+ : no change
2. Normal, unvaccinated	(+)CMI-; (+)Ab-	CMI+; Ab+ : primary vaccination
3. Thymic dysplasia	(-)CMI-; (+)Ab-	CMI-; Ab+ : progressive vaccinia ↓ VIG ↓ CMI-; Ab+ : progressive vaccinia
4. Bruton's syndrome	(+)CMI-; (-)Ab-	CMI+; Ab- : primary immunization or CMI-; Ab- (CMI "overwhelmed") : progressive vaccinia ↓ VIG ↓ CMI+; Ab+ : CMI restored—recovery
5. Swiss syndrome	(-)CMI-; (-)Ab-	CMI-; Ab- : progressive vaccinia ↓ VIG ↓ CMI-; Ab+ : progressive vaccinia
6. Acquired deficiencies (e.g., lymphoma)	(-)CMI-; (-)Ab-	CMI-; Ab- : progressive vaccinia ↓ VIG ↓ CMI+; Ab+ : CMI restored—recovery

Fig. 3.8. The response of normal individuals and individuals with immunological defects to vaccination. Progressive vaccinia is associated with a defective cell-mediated immune response, but under some circumstances vaccinia-immune globulin can be useful (see text). CMI = cell-mediated immunity; Ab = antibody production; VIG = vaccinia-immune globulin; (+) or (-) = potential for CMI or Ab response; + or - = presence or absence of appropriate response. (Based on Freed et al., 1972.)

cells coincides with the disappearance of primary cytotoxic T-cell activity, which falls off rapidly after viral clearance (Gardner & Blanden, 1976). After mediating viral clearance, primary cytotoxic T cells apparently dedifferentiate and lose their lytic capacity, and on restimulation with antigen, which occurs on reinfection, the sequence is reversed. In addition, in the primed individual there are memory helper T cells whose functional activity can only be expressed in the presence of antigen, when they elaborate factors that amplify the functions of B cells and of other subclasses of precommitted T cells.

The role of memory T cells in persisting immunity to orthopoxvirus infections increases in importance as the interval between

primary and secondary infections increases, since as long as pre-existing antibody of the correct specificity persists this probably aborts infection at the portal of entry. Later, the ability to mount a rapid cell-mediated immune response would assist greatly in limiting the growth of virus and extension of the infectious foci.

### REDUCING THE RISKS OF VACCINATION

Vaccination was introduced and its efficacy established by the most relevant and stringent criterion, its ability to provide protection against smallpox, almost a century before immunological techniques were developed.

After smallpox had been eliminated from Europe and North America in the 1950s, the public in these countries did not readily tolerate the degree of illness—not to say the occasional episodes of severe illness or even deaths, which occurred, for example, in eczematous children and those with an immunological deficiency—that were associated with standard smallpox vaccination. Two ways were sought to provide immunization against smallpox without the attendant risks of severe disease: the use of attenuated strains of vaccinia virus and the use of inactivated vaccines.

The assessment of the efficacy of either of these kinds of vaccine presented obvious problems, since the real criterion for their value was the ability of the vaccine to protect against smallpox and the durability of this protection. On ethical and practical grounds it was not possible to test new vaccines in this way, so two other criteria were used in their assessment: the neutralizing antibody response and protection against challenge inoculation of standard vaccine, supplemented, in experiments with animals, by protection against an otherwise lethal challenge with a suitable orthopoxvirus.

By all three tests the standard vaccine strains provided excellent protection against smallpox. The situation was less clear-cut with attenuated vaccinia virus vaccines, which are discussed at some length in Chapter 11. There appeared to be serious deficiencies in protection when inactivated vaccines were used, the reasons for which are outlined below.

### Inactivated Virus Vaccines

The production of an inactivated smallpox vaccine seemed a feasible procedure, since it was relatively easy to grow and purify large amounts of vaccinia virus. Many methods of inactivation were tested (Kaplan, 1969; Turner et al., 1970), including heat, formaldehyde, ultraviolet irradiation, photodynamic inactivation and gamma irradiation.

As described in Chapter 2, there are major antigenic differences between the surface antigens of enveloped and non-enveloped virions, both of which are infectious. Smallpox vaccine, however it was grown, was prepared in such a way that it consisted predominantly of non-enveloped virions. The infection provoked by vaccination with live vaccine led to the development of both

enveloped and non-enveloped virions and the full range of humoral and cellular immune responses. In contrast, inactivated virions failed to provoke a humoral response to the envelope antigens (Appleyard et al., 1971; Turner & Squires, 1971; Payne, 1980), nor did they stimulate the production of cytotoxic T cells (Ada et al., 1981).

Experiments with inactivated vaccines highlighted the lack of correlation between levels of neutralizing antibody (measured against non-enveloped virions) and protection. Thus immunization of rabbits with a vaccinia virus "soluble antigen" gave a good antibody response and protection against intradermal challenge with vaccinia virus, but resistance to the more virulent rabbitpox virus was less than that induced by live vaccinia virus, despite the fact that the live virus induced much less antibody (Appleyard & Westwood, 1964b). Rabbits immunized by multiple intradermal injections followed by 6 intravenous injections of heat-inactivated vaccinia virus developed high titres of neutralizing antibody, but even after this intensive course there was only partial protection against challenge infection with rabbitpox virus (a virulent strain of vaccinia virus) (Madeley, 1968). Similarly, rabbits immunized with large doses of vaccinia virus inactivated by formaldehyde or ultraviolet irradiation developed extremely high titres of neutralizing antibody (tested against non-enveloped virions), but they remained susceptible to generalized rabbitpox infection, although protected from death (Boulter et al., 1971). The importance of antibody against enveloped virions was most clearly demonstrated by experiments on the passive transfer of resistance with antiserum (Table 3.5). Antisera against inactivated virus, with very high levels of neutralizing antibody to non-enveloped but none to enveloped virions, provided much weaker protection against challenge infection than apparently much lower titres of antibody induced by infectious virus, which, however, contained both kinds of neutralizing antibody.

More recently, Olsen et al. (1977) reported that an inactivated vaccine prepared by mechanically disrupting monkeypox virions protected monkeys against disease when they were challenged with active monkeypox virus, although it did not prevent infection. There were two significant features in these experiments. First, immunization was carried out with the homologous virus. The second—

Table 3.5. Comparison of the protective activity of three types of antiserum administered passively to rabbits before challenge infection with rabbitpox virus<sup>a</sup>

Against	Antiserum		Response to challenge	
	Source	Neutralization titre	Fever	Death
Inactivated vaccinia virus	Horse	900 000 <sup>b</sup>	12/12	5/12
	Sheep	500 000 <sup>b</sup>	5/5	4/5
Live vaccinia virus	Sheep	150 000 <sup>c</sup>	4/5	0/5
	Rabbit	19 000 <sup>c</sup>	8/10	0/10
Live rabbitpox virus	Rabbit	32 000 <sup>c</sup>	0/5	0/5
None	—	—	18/18	15/18

<sup>a</sup> From Boulter et al. (1971).<sup>b</sup> Measured against non-enveloped virions; no neutralizing antibodies to enveloped virions.<sup>c</sup> Measured against non-enveloped virions; neutralizing antibodies to enveloped virions also present.

and more important—feature was that, although the inactivated preparation had no haemagglutinating capacity, it elicited the production of haemagglutinin-inhibiting as well as neutralizing antibodies, demonstrating that the method of inactivation left at least some of the envelope antigens intact.

It also appears that inactivated virus provokes a rather different kind of cell-mediated immune response from that found after infection, eliciting delayed hypersensitivity T cells but not cytotoxic T cells (Ada et al., 1981), perhaps because the surface antigens involved in infected cells are not produced, or because the mode of inoculation results in too localized and immobile an antigenic mass. Indeed, the delayed hypersensitivity reaction itself was deficient in rabbits immunized with inactivated vaccine. For example, Turner et al. (1970) and Turner & Squires (1971) found that inactivated vaccines did not produce an obvious delayed hypersensitivity response, although the animals responded more rapidly than did the controls to challenge inoculation with live virus.

Thus, inactivated vaccines suffered from two defects: they failed to elicit antibodies that neutralized enveloped virions and they failed to provoke the production of cytotoxic T cells. In addition, the adverse effects of inactivated measles virus vaccines, which became evident in the mid-1960s (Fulginiti et al., 1967), made public health authorities reluctant to consider another inactivated virus vaccine when there was already a successful live virus vaccine available. Nevertheless, in an effort to reduce the incidence and severity of postvaccinal encephalitis, formalin-inactivated vaccine ("vaccinia-antigen") was used in the German Democratic Republic and the Federal Republic of

Germany during the late 1960s (see Chapter 11) for a "priming" vaccination, followed by vaccination with standard vaccine. Subsequently, Marennikova & Macevič (1975) showed that pre-immunization of rabbits with vaccine inactivated by <sup>60</sup>Co gamma-irradiation greatly enhanced their response to vaccination with active vaccine given 7–60 days later, both in the titre of antibody produced and in its rate of production. Pre-immunization reduced the incidence of viraemia in the rabbits 4–5 days after vaccination with live virus. Preliminary human trials on the use of this preparation as a priming antigen were carried out in eastern Europe in 1977 (see Chapter 11).

### NON-SPECIFIC MECHANISMS INVOLVED IN HOST DEFENCE

The efficacy of vaccination and the increased susceptibility of individuals with certain immunological defects illustrate clearly the great importance of the immune response in orthopoxvirus infections. There are nevertheless a number of defence mechanisms against viral infections whose activity is not specific in an immunological sense. Most of these are ill-understood and it is difficult to evaluate their importance in orthopoxvirus infections.

#### Body Temperature

As outlined in Chapter 2, determination of the ceiling temperature of viral replication is a useful laboratory method of distinguishing between certain orthopoxviruses and between variola major and certain strains of variola minor virus. In animal models, body tempera-

ture has a dramatic effect on the severity of the leporipoxvirus disease, myxomatosis (Marshall, 1959), and mice housed at 2 °C are about 100 times more susceptible to mousepox than those maintained at 20 °C (Roberts, 1964).

There is no evidence that raised body temperature affected the progress of variola major; severe cases (flat-type and haemorrhagic-type smallpox) were often associated with higher temperatures than those found in ordinary-type smallpox. However, Dumbell & Wells (1982), comparing variola major and alastrim (variola minor) viruses, found that many fewer virions of alastrim (variola minor) virus (which had the lower ceiling temperature) than of variola major virus were released from infected cells when the temperature was raised. The decreased dissemination of virus could act in concert with developing immunity to reduce the severity of variola minor.

### Nutrition

Almost any severe nutritional deficiency will interfere with the activity of phagocytes, and the integrity of the skin and mucous membranes is impaired in many types of nutritional deficiency (review: Scrimshaw et al., 1968). Immunoglobulin levels, antibody responses and the numbers of circulating B cells are generally normal in cases of moderate to severe malnutrition, but cell-mediated immunity is consistently impaired, whether measured by cutaneous delayed hypersensitivity tests or by the numbers of circulating T cells (Chandra, 1979). The number of null cells—i.e., cells without the surface characteristics of T or B cells, which suppress the activity of other lymphocytes—was relatively increased in cases of malnutrition. It will be recalled that the proportion of such cells was substantially increased in patients with smallpox and that there seemed to be a correlation between the height of the null cell count and the prognosis (Jackson et al., 1977).

Little information is available about the effect of malnutrition on smallpox, although it seems clear that its effects were not as dramatic as those seen in measles in young children in many African countries. The mortality of variola major in unvaccinated infants was so high that it was difficult to determine whether nutritional deficiency was important. However WHO epidemiologists working in Ethiopia and Somalia noticed that

1961

**Plate 3.11.** Rijk Gispén (b.1910). Formerly Director of the National Institute of Public Health at Bilthoven, Netherlands. Gispén was an important contributor to the immunology of orthopoxvirus infections from the 1950s to the 1970s. He was the first to develop methods of differentiating between antibodies due to infection with monkeypox, variola and vaccinia viruses.

variola minor was much more severe in malnourished than in well-nourished infants.

The occurrence of blindness after smallpox is said usually to have been associated with secondary bacterial infection or nutritional deficiencies.

### Age

Among unvaccinated persons, smallpox produced its highest mortality in the very young and the aged, and its lowest in the age group 5–20 years, but there is no obvious explanation for these age-related effects except in so far as the mechanisms of specific and non-specific resistance function less effectively at the extremes of life.

### Hormonal Effects

Pregnancy had a very pronounced effect on the severity of smallpox. Especially in variola major, pregnant women were much more likely than any other category to suffer from haemorrhagic-type smallpox (see Chapter 1). Pregnant women have elevated levels of 17-dihydroxycorticosteroids, which have an anti-inflammatory effect, depress the immune

response and inhibit interferon production. Studies in rabbits infected with vaccinia virus showed that cortisone diminished the local inflammatory reaction and increased viral titres in the blood and internal organs (Bugbee et al., 1960). Vaccination could produce severe effects in humans receiving corticosteroid therapy.

Rao et al. (1968b) found that cortisone converted experimental smallpox in monkeys from a non-lethal into a lethal disease. Viraemia was greatly enhanced in intensity and persisted for a longer time, the internal organs contained much more virus than in control animals, and there were numerous haemorrhages in the lungs and in the mucous membrane of the gastrointestinal tract.

### Interferon

Interferons are a family of proteins of low molecular weight produced by a wide variety of cells. Lymphocytes produce a different kind of interferon (gamma-interferon) from fibroblastic cells, but all kinds of interferon may render cells that take them up more resistant to viral infection. Vaccinia virus was the first virus shown to be sensitive to interferon in an intact animal. Isaacs & Westwood (1959) showed that interferon prepared in rabbit cells protected rabbits completely against intradermal infection with a large dose of vaccinia virus, when given a day before the virus was administered, and against a smaller dose when both were administered intradermally on the same day. However, Blanden (1970, 1971a) showed that passively administered interferon had no effect on recovery from mousepox. Interferon seems unlikely to have played a role in determining differential host responses in smallpox, but it may have been important in determining the differences in severity of inoculation smallpox and the "natural" disease.

### *Interferon and inoculation smallpox*

Inoculation smallpox (variola) is much milder than "natural" smallpox (see Chapters 1 and 6). Following the demonstration that vaccinia scabs contained interferon, Wheelock (1964) suggested that the presence of interferon in scab material that was used for variolation might have so interfered with the replication of the inoculated virus that the

consequent disease was milder than smallpox acquired by the inhalation of virus contained in oropharyngeal secretions. This is unlikely to be the complete explanation; intradermal inoculation was associated with a shorter incubation period and the immune response would have been differently stimulated, but interferon in the inoculum and possibly the local production of interferon induced by inactivated virus in the inoculum may have played a role.

### GENETIC ASPECTS OF RESISTANCE TO SMALLPOX

Because of the availability of lines of mice of known genotypes and of congenic recombinant strains (Klein, 1975), these animals are uniquely suitable for the analysis of genetic resistance to viral infection. Studies with mousepox (Brady et al., 1956; Schell, 1960a,b; Wallace et al., 1985) demonstrated that genetic factors played a major role in determining their response to mousepox.

It is clearly not possible to analyse the genetic component of the resistance of humans to smallpox in this way. Nevertheless, it is worth examining whether any human population groups showed unusual resistance or susceptibility, independent of the effects of vaccination.

### Natural Selection for Resistance to Smallpox

Once again, an animal model may provide a useful lead in understanding what may have happened in smallpox. Myxomatosis, a severe generalized poxvirus disease in European rabbits (*Oryctolagus cuniculus*), provides the best example of rapid enhancement of the level of genetic resistance in a population as a result of exposure to the disease (Fenner & Ratcliffe, 1965; Fenner, 1983). Although it was nowhere near as lethal a disease as myxomatosis, smallpox was severe enough to have had a selective effect for resistance among humans exposed to infection over many centuries, as in India and China and to a lesser extent in Europe.

Reports of smallpox in the 16th and 17th centuries among the Indian tribes of North America (Stearn & Stearn, 1945) and in Brazil (Hemming, 1978) describe the extreme severity of smallpox in these hitherto unexposed

populations. Hemming notes that in Brazil the Portuguese colonists observed that Negro slaves, when they got smallpox, suffered less severely than the Amerindian slaves; most of the European invaders themselves were immune because of infections sustained in their childhood. Although several other factors besides lack of genetic resistance could have been involved in exacerbating the effects of the disease among the Amerindians—notably the severe social disruption accompanying the first outbreaks—it is tempting to consider that their extreme susceptibility was in part related to the absence of previous selection for resistance to smallpox.

From what we now know about the relation between the major histocompatibility genes and resistance to viral infections (review: Zinkernagel, 1979), it would have been interesting to investigate the relation between HLA groups and susceptibility to smallpox; experiments with mousepox showed that at least part of the genetic resistance to this disease was associated with the H-2 complex in the mouse (R.V. Blanden, personal communication, 1981). The opportunity to do this never arose, but Vries et al. (1977) showed that after vaccination with vaccinia virus, the lymphocytes of Dutch soldiers belonging to a particular HLA group (Cw3) responded significantly less effectively than others in an *in vitro* lymphocyte transformation test using vaccinia virus as antigen (a measure of cell-mediated immunity). This HLA group made up 30% of the general population in the Netherlands, compared with 83% of the low-responder group.

During the 1950s and 1960s, a great deal of information was accumulated on the distribution of ABO blood groups in different populations. Pettenkofer et al. (1962) claimed that there was a correlation between past histories of smallpox epidemics and the distribution of ABO blood group frequencies, and that in India there were different degrees of scarring in persons of blood groups B and O compared with those of blood groups A and AB. However, investigations by several different teams of workers in India (Bhattacharyya et al., 1965; Downie et al., 1965b; Helmbold et al., quoted by Vogel & Chakravarti, 1966; Sukumaran et al., 1966), in Brazil (Krieger & Vicente, 1969), and in Zaïre (Lambotte & Israel, 1967) found no evidence of a correlation between the incidence and severity of smallpox and the ABO blood group of the subjects. Nor was there any

correlation between ABO blood groups and the occurrence of neurological or dermal complications of vaccination (Gurvich et al., 1980). Most human geneticists now doubt whether smallpox was an important selective agent in blood group ABO polymorphism (Mourant et al., 1978).

## SUMMARY: THE PATHOGENESIS OF SMALLPOX

Although a good deal of speculation and extrapolation from various model systems will inevitably be involved, it is worth attempting to summarize the results of the work presented in this chapter in the form of a comprehensive picture of the pathogenesis of smallpox in man.

### Viral Entry and Infection

Infection usually occurred by the implantation on the oropharyngeal or respiratory mucosa of virus released from lesions in the mouth, nose and pharynx into the nasal and oropharyngeal secretions of the source case during the first week of rash. Such material probably consisted of well-dispersed virions and would have been relatively free of interferon. In contrast, scab material usually consisted of large fragments of inspissated material with infectious virions bound within a dense, hard fibrin mesh, which contained a substantial amount of interferon, and from which it was difficult to release virus except by mechanical grinding. These features probably accounted for the much lower transmissibility associated with scabs, compared with oropharyngeal secretions.

The initial site of lodgement was usually somewhere in the oropharynx, nasopharynx or the lower respiratory tract. Whatever cells were initially infected, macrophages would soon have become infected and by about the 3rd day would have entered the lymphatics and thus reached the regional lymph nodes. They might also have entered the bloodstream at this stage, or in any case by about the 4th day, after a brief delay and replication in the draining lymph nodes.

The initial infection in the oropharynx or respiratory tract was silent, producing neither symptoms nor a local lesion that could be recognized clinically, or by autopsy in cases that died early.

### Spread through the Body

The inevitable lack of careful postmortem examinations of cases of smallpox dying from other causes during the incubation period of the disease, combined with the paucity of careful postmortem or virological examinations of acutely fatal cases, makes it difficult to assess precisely where the virus replicated before the secondary viraemia occurred, at the time of the onset of symptoms. The most likely places were the lymphoid organs (spleen, bone marrow and lymph nodes), but extensive necrosis did not occur there. Viraemia was largely cell-associated and most virions that existed free in the plasma were probably in the enveloped form.

The reasons for the localization of virus in the skin and the characteristic "centrifugal" distribution of the rash are unknown. Probably, infected macrophages migrated from small vessels in the dermis into the epidermis, where they proceeded to cause infection of the cells of the Malpighian layer. Oedema and ballooning degeneration followed, with reticulating degeneration and splitting of the epidermis that produced a multiloculated vesicle. Later there was a migration of polymorphonuclear cells into the lumen of the developing vesicle, so that its contents became pustular.

### The Immune Response

The early lodgement of infected macrophages in the lymph nodes, bone marrow and spleen would have stimulated an immediate immune response to the wide variety of viral antigens produced by infected cells. The first component of the immune system to become manifest was the production of cytotoxic T cells, which, because of their affinity to the early viral antigens found in the cell membranes, promptly destroyed many infected cells before they produced virions. Later, neutralizing antibodies appeared, some of which were directed against the viral envelope (which contained several of the antigens also found in the surface membrane of infected cells); others were able to neutralize the infectivity of intracellular non-enveloped virions, which were released when necrotic cells were disrupted. The activity of cytotoxic T cells and the titre of antibodies increased as time progressed. In addition, infected macrophages and lymphocytes, as well as infected

cells in the skin, produced interferon. In cases in which the early cellular immune response was vigorous, replication of the virus was inhibited and the skin lesions were restricted, so that a discrete rash developed.

If the cellular immune response was grossly deficient, the case may have presented as flat-type smallpox. Haemorrhagic-type smallpox was associated with unrestricted replication of the virus especially in the bone marrow, so that a much higher viraemia developed than in most non-haemorrhagic cases and megakaryocyte destruction in the bone marrow led to defects in the blood coagulation mechanism. Further, the immune response, both humoral and cellular, was defective in haemorrhagic-type smallpox, which was particularly frequent in pregnant women, probably because of their increased corticosteroid secretions.

### Death or Recovery

The outcome of the infection was either death or recovery, with or without sequelae. Except in haemorrhagic-type smallpox, the cause of death was obscure, since none of the "vital organs" (brain, lungs, heart, kidneys, liver) seemed to have been severely damaged in fatal cases. It was ascribed to severe toxæmia, perhaps due in part to the effect of circulating immune complexes. Death in very severe cases (confluent ordinary, flat and haemorrhagic types) was associated with a high and prolonged viraemia and a poor humoral antibody response, and probably a defective cellular immune response as well.

The commonest sequelae were pockmarks, which could occur all over the body but were usually most profuse on the face because of the large number of sebaceous glands there and the deeper pitting associated with their involvement. Encephalitis, with a pathogenesis as obscure as that of postvaccinal encephalitis, occurred in about 0.2% of cases of variola major. It was somewhat rarer in variola minor, but a relatively more important cause of death in that disease. Arthritis and osteomyelitis sometimes occurred, though often they were recognized only after recovery. Blindness was an important but rare complication, usually occurring in cases in which there was malnutrition and/or secondary bacterial infection.

Recovery was accompanied by long-lasting immunity to reinfection with variola virus. Heterologous immunity—e.g., to vacci-

nation—was much less prolonged, especially in cases of variola minor. Variola virus did not persist in the body after recovery;

thus, previously infected persons, even when immunosuppressed, have shown no recurrence of infectivity.

### INTRODUCTION

Chapters 1 and 3 were concerned with smallpox as a disease of individual human beings, discussing such problems as how the virus entered the body and spread through it,

how the body reacted and what symptoms were produced, and how the virus was shed. Since smallpox was an infectious disease, there is another dimension to its study besides its effect on individual patients—namely, its behaviour in human populations. This di-

mension constitutes the epidemiology of the disease, which involves examination of the incidence of smallpox and the mortality attributable to it, over time and in different countries and regions; the various determinants of its occurrence and spread; its maintenance as an endemic disease; and the causes of epidemics. These considerations were of fundamental importance in its control and eventual eradication.

### THE MORBIDITY AND MORTALITY OF SMALLPOX IN THE 20TH CENTURY

In Chapter 5 we describe how smallpox spread throughout the world, first through Asia, beginning in the 1st century AD, and then into Europe and northern Africa from about AD 700 onwards. With European colonization the disease was carried to Central, South and North America and southern Africa in the 16th and 17th centuries. By the time vaccination was introduced, at the end of the 18th century, the distribution of smallpox was world-wide. It was endemic everywhere, except in remote areas with sparse populations, such as Australia, New Zealand and the islands of the Pacific, Atlantic and Indian Oceans. Periodically it caused disastrous epidemics in many smaller island communities and then died out, as, for example, in Iceland, the islands of the Caribbean, Hawaii, Tahiti, Mauritius and the smaller islands of what were then the Netherlands East Indies (Hirsch, 1883).

#### Secular Changes in the Global Occurrence of Smallpox

By the early years of the 20th century endemic smallpox had been eliminated from a few of the countries of northern Europe with small populations, although importations from more densely populated neighbouring countries occurred almost every year (see Chapter 8). However, until current statistics began to be published by the Health Organisation of the League of Nations in 1922 (Howard-Jones, 1975), there was no mechanism for systematically collecting and disseminating information on the incidence of smallpox in different countries. National data for the early years of the 20th century were compiled by Low (1918) and consolidated

figures for the years 1920-1947 were published by the Interim Commission of the World Health Organization (Fabre, 1948).

Weekly and consolidated annual figures for reported cases of smallpox in different countries were published by the World Health Organization after 1948. These figures, supplemented by investigations carried out by the WHO Smallpox Eradication unit, were used for the tabulation of reported cases of smallpox by country and by WHO region provided in the *Final Report of the Global Commission for the Certification of Smallpox Eradication* (World Health Organization, 1980). Further supplemented by studies conducted by the authors of the present book, these data were used for the detailed tabulation of reported cases of smallpox in the larger countries of the world presented in Chapter 8. These official data reflect only reported cases, and, as will be shown in a later section, smallpox was grossly underreported in most countries. The figures convey an impression of the ebb and flow of the disease in various countries, but they give little idea of its true incidence.

More relevant in the present context is a global overview of secular trends in the numbers of countries in which smallpox was endemic during the period from 1920 until its eradication (Fig. 4.1). To obtain the data for this, all available sources of information were consulted, and the assumption was made that smallpox was persistently endemic between the 1920s and the 1940s in countries in which in the 1950s it appeared to be a long-established endemic disease, even though some of these countries had failed to report its occurrence to the Health Organisation of the League of Nations during that period. The data are plotted by 5-year intervals prior to 1958 and annually thereafter; they show for each continent the secular changes in the numbers of countries in which smallpox was endemic. In terms of the global eradication of smallpox, important administrative decisions were taken in 1959, when the World Health Assembly first launched a programme for global eradication, and in 1967, when the Intensified Smallpox Eradication Programme was initiated (see Chapters 9 and 10).

#### *The period 1920-1958*

In 1920 smallpox was endemic in most countries, being present in 124 and absent

Fig. 4.1. Numbers of countries and territories in which smallpox was endemic between 1920 and 1978, arranged by continent. The figures in brackets indicate the numbers of countries and territories involved. Their names (as of 1986) are listed below.

**Africa:** Algeria, Angola, Benin, Botswana, Burkina Faso (Upper Volta), Burundi, Cameroon, Central African Republic, Chad, Congo, Côte d'Ivoire, Djibouti, Egypt, Equatorial Guinea, Ethiopia, Gabon, Gambia, Ghana, Guinea, Guinea-Bissau, Kenya, Lesotho, Liberia, Libyan Arab Jamahiriya, Madagascar, Malawi, Mali, Mauritania, Morocco, Mozambique, Namibia (South West Africa), Niger, Nigeria, Rwanda, Senegal, Sierra Leone, Somalia, South Africa, Sudan, Swaziland, Togo, Tunisia, Uganda, United Republic of Tanzania, Zaire, Zambia, Zimbabwe.

**Americas:** Argentina, Belize, Bolivia, Brazil, Canada, Chile, Colombia, Costa Rica, Cuba, Ecuador, El Salvador, French Guiana, Guatemala, Guyana, Honduras, Jamaica, Mexico, Nicaragua, Panama, Paraguay, Peru, Suriname, USA, Uruguay, Venezuela.

only from all the countries of Oceania and 16 countries in the other 4 continents. The only countries of Oceania with populations large enough to have supported endemic smallpox were Australia and New Zealand, which were protected by distance and an effective system of seaport quarantine from all but a very few importations, most of which were controlled at the port of entry.

By 1920 endemic smallpox in Europe had been eliminated only from Denmark, the Netherlands, Norway and Sweden. Subsequently the situation improved quite rapidly,

**Asia:** Afghanistan, Bahrain, Bangladesh, Bhutan, Burma, China, Democratic Kampuchea, Democratic Yemen, Democratic People's Republic of Korea, Hong Kong, India, Indonesia, Islamic Republic of Iran, Iraq, Israel, Japan, Jordan, Kuwait, Lao People's Democratic Republic, Lebanon, Loro Sae (East Timor), Macao, Malaysia, Mongolia, Nepal, Oman, Pakistan, Philippines, Qatar, Republic of Korea, Saudi Arabia, Singapore, Sri Lanka, Syrian Arab Republic, Thailand, United Arab Emirates, Viet Nam, Yemen.

**Europe:** Albania, Austria, Belgium, Bulgaria, Cyprus, Czechoslovakia, Denmark, Finland, France, German Democratic Republic, Federal Republic of Germany, Greece, Hungary, Iceland, Ireland, Italy, Luxembourg, Malta, Netherlands, Norway, Poland, Portugal, Romania, Spain, Sweden, Switzerland, Turkey, USSR, United Kingdom, Yugoslavia.

**Oceania:** Australia, Fiji, French Polynesia, Guam, Kiribati, Mariana Islands, Marshall Islands, Nauru, New Caledonia, New Zealand, Papua New Guinea, Samoa, Solomon Islands, Tonga, Tuvalu, Vanuatu.

so that by 1935 endemic smallpox had been eliminated from 25 countries, although it remained relatively common in Portugal, Spain, the USSR and the United Kingdom. The last endemic case in the USSR was reported in 1936 (see Chapter 8). Elsewhere in Europe the downward trend continued, and the continent was free of endemic smallpox by 1953.

In the Americas, tens of thousands of cases of smallpox were reported annually up to the late 1930s, variola major in Mexico and some South American countries and mostly variola

minor in other South American countries and the USA. Smallpox was eliminated from the Central American countries between 1920 and 1951 and from Mexico in 1951. Endemic variola major had been eliminated from the USA in 1926 but variola minor persisted until the late 1940s. Smallpox continued to be endemic in the larger countries of South America until 1950, when a steady decline began. In that year a regional eradication campaign for the Americas was initiated by the Pan American Sanitary Organization (later renamed the Pan American Health Organization) (see Chapter 9) and the incidence continued to fall until, by 1958, smallpox remained endemic in only 6 countries.

The situation was not nearly as good as this in Asia and Africa, the continents in which reporting was the least reliable. The number of endemic countries in Asia declined slowly, endemic smallpox being eliminated from Indonesia, Malaysia, the Philippines and Sri Lanka by 1938, only to be reintroduced into these countries during the disruption caused by the Second World War. After that there was a slight but steady improvement, mainly in the smaller countries of eastern Asia, but the disease appeared to be largely unchecked in the Indian subcontinent and was still endemic in some 40% of the countries of Asia in 1958.

In Africa progress was even slower, except for the gradual reduction in the number of reported cases and the elimination of endemic smallpox in the countries of northern Africa and some of the small sparsely populated countries in southern Africa. During this period successful country-wide elimination did not always mean that subsequent importations would be successfully contained. For example, after the elimination of endemic smallpox from Egypt in the mid-1930s, variola major was reintroduced during the Second World War and became endemic again, producing several thousand reported cases in 1943–1945 (Tulloch, 1980). There were similar exacerbations after the Second World War in Algeria, Libya and Morocco. In most countries in Africa south of the Sahara smallpox was apparently almost as common in 1958 as it had been two decades earlier.

#### *The period 1959–1966*

In 1959 the Twelfth World Health Assembly adopted a resolution introduced by the USSR calling for the world-wide eradication

of smallpox (see Chapter 9), confident in the knowledge that eradication had by then been achieved in Europe and in North and Central America. The situation in South America appeared to be manageable, and indeed the number of endemic countries decreased until, by 1967, smallpox remained endemic only in Brazil. The real problem was posed by the developing countries of Africa and Asia. During the few years between 1959 and 1966 there were substantial gains in Asia, the most important of which was the elimination of endemic smallpox from China. This was achieved by 1961 and was due entirely to a national initiative. Smallpox, however, remained rampant in the Indian subcontinent. Some progress was made in western and southern Africa, but in 1966 the disease was still endemic in 27 of the 47 countries of Africa.

#### *The period 1967–1978*

As outlined in Chapter 9, by 1967 it was clear that—the Twelfth World Health Assembly resolution notwithstanding—the global eradication of smallpox could not be achieved without greater financial, administrative and scientific support. In that year the Intensified Smallpox Eradication Programme was instituted, supported by funds from the WHO regular budget, and a Smallpox Eradication unit was established at WHO Headquarters in Geneva. At the same time, the WHO regional offices responsible for countries in which endemic smallpox was present assumed an active role in organizing and coordinating country programmes. The rapid fall in the number of countries with endemic smallpox over the period 1967–1978 is illustrated in Fig. 4.1 and described at greater length in Chapter 10.

By the time that the Intensified Programme was launched, smallpox had been eradicated in South America, except for Brazil, in which the last case in the Americas occurred in 1971. Results were achieved rapidly in the countries of western and central Africa in a campaign which began in 1967. Steady progress occurred in eastern, south-eastern and southern Africa. The biggest challenge confronting the Intensified Smallpox Eradication Programme was the eradication of variola major from the Indian subcontinent, a relatively slow process, which was, however, achieved by 1975. By 1976 the only remaining endemic country was Ethiopia, in

which variola minor persisted and spread to Somalia, eventually to be eradicated from the Horn of Africa, and the world, by the end of 1977.

## Smallpox Incidence and Incidence Rates

### *General considerations*

The countries and territories listed beneath Fig. 4.1 vary enormously in size and population, from China and India on the one hand, each with populations of several hundred millions, to Bahrain and Swaziland, with populations of a few hundred thousand, on the other.

The numbers of cases of smallpox reported annually to the international health authorities by the governments of different countries varied greatly in accuracy. Those obtained from non-endemic countries with well-established health services, reporting small outbreaks due to importations, were probably the most accurate, although even here distortions sometimes occurred, owing to the suppression of reports (see Chapter 23). The reported numbers of cases in endemic countries for the earlier years of the period under review—often countries with grossly inadequate reporting systems—greatly understated the true incidence of the disease. Even in countries in which smallpox was an important public health problem and there were reasonable health services, reporting was incomplete

before and even after national eradication campaigns had been launched (see below). However, the incidence of reported cases (Fig. 4.2) provides some indication of the true incidence of smallpox in the countries in which it was endemic in 1967. At the start of the Intensified Smallpox Eradication Programme, the reported incidence amounted to perhaps 1–2% of the true figure.

During the Intensified Programme several efforts were made to determine what proportion of cases was actually reported in countries with endemic smallpox. Two kinds of assessment were made. The first contrasted the reported figures with the incidence as estimated by pockmark surveys carried out in selected age groups; the second was based on a comparison, in India and Ethiopia, of the reported incidence before and after efficient surveillance and case-reporting systems were established, during the late stages of the eradication campaigns in each country.

### *Assessment by facial pockmark surveys*

First employed by Dr Jacobus Keja in Nepal and then in Indonesia (see Chapter 13), this method was later used by Foster (WHO/SE/72.34) and Hughes et al. (1980) for assessing the efficiency of reporting in western Africa and Bangladesh respectively. The method involved the examination of persons in appropriate age groups for facial pockmarks (Table 4.1). For survey purposes a

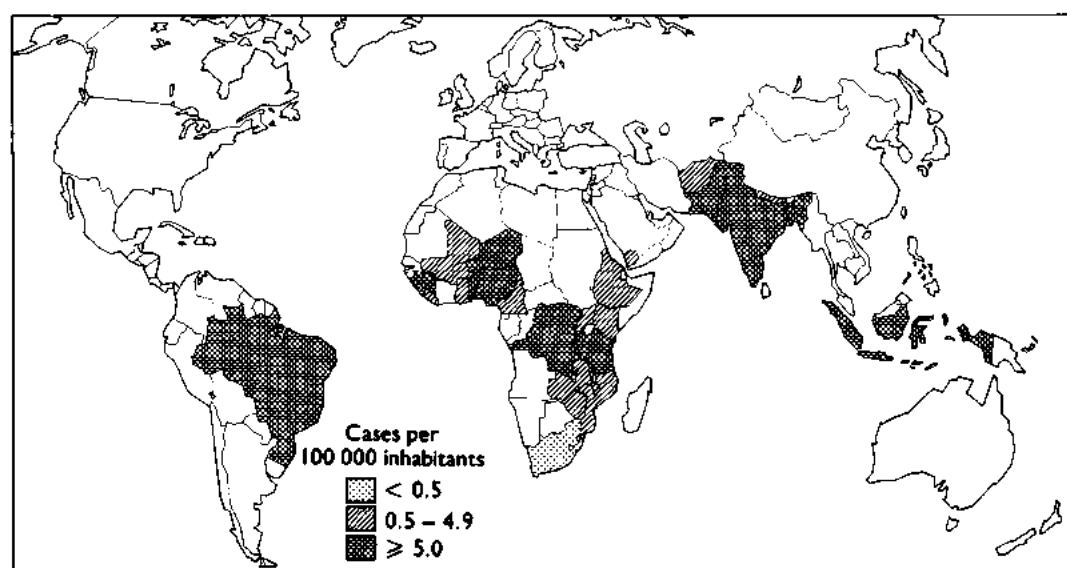

Fig. 4.2. Incidence of reported cases in the 31 countries and territories in which smallpox was endemic in 1967.

Table 4.1. Efficiency of reporting of smallpox in Kano (an urban area in Nigeria), as estimated from facial pockmark surveys in the age group 0-14 years<sup>a</sup>

(1) <i>Estimated population in the age group 0-14 years</i>	
Total population—500 000, of which 223 000 (44.6%) were 0-14 years old.	
(2) <i>Estimation of total number of cases of smallpox in the age group 0-14 years</i>	
Observed frequency of smallpox pockmarks in a sample survey of the age group 0-14 years—3.7%.	
Estimated number of children aged 0-14 years with facial pockmarks— $3.7/100 \times 223\ 000 = 8250$ .	
Proportion of children aged 0-14 years who retained pockmarks for at least 1-4 years—55%.	
Estimated number of children aged 0-14 years who had smallpox and survived— $\frac{8250}{55/100} = 15\ 000$ .	
Smallpox case-fatality rate in children aged 0-14 years—13%.	
Estimated total number of cases of smallpox in the age group 0-14 years— $\frac{15\ 000}{87/100} = 17\ 250$ .	
(3) <i>Estimation of total number of cases of smallpox during the last 15 years</i>	
Proportion of smallpox cases which normally occur in the age group 0-14 years—50%.	
Estimated total number of smallpox cases during the last 15 years— $\frac{17\ 250}{50/100} = 34\ 500$ .	
(4) <i>Calculation of the efficiency of reporting smallpox</i>	
Reported number of smallpox cases during the last 15 years—2805.	
Reporting efficiency— $\frac{2\ 805}{34\ 500} = 8.1\%$ .	

<sup>a</sup> Based on Foster (WHO/SE/72.34).

positive case was defined as one which had at least 5 characteristic round, depressed facial scars, a millimetre or more in diameter. By correcting for the observed rate of smallpox mortality in a selected age group, for mortality due to other causes and for the disappearance of facial scars over time (which varied according to the age at which the person acquired smallpox and was determined for each age group and area) it was possible to estimate the incidence rates of smallpox within the sampled population. The smallpox incidence in the entire population could be estimated by correcting for the age distribution of cases, and this figure could then be compared with the number of officially reported cases.

Using this procedure, Foster calculated that the efficiency of reporting was 1.3% in rural areas of Nigeria and 8.1% in Kano, an urban centre. Hughes et al. (1980), using a similar procedure, found that as late as 1972 reporting efficiency in Bangladesh was only about 12%, but rose in the succeeding years, when active searches for unreported cases were intensified, to over 80% (see Chapter 16, Fig. 16.9). The health services in Bangladesh and Nigeria were more extensive and better developed than those in most endemic countries at that time, so that these estimates reflect better-than-average situations.

#### *Changes in the numbers of reported cases after improved surveillance*

The highest numbers of cases for many years were often reported during the periods

just before country-wide elimination was achieved, since by this time good surveillance systems were in operation. For example, the highest figure for India since the 1950s was 188 003 in 1974, the year before the attainment of eradication. The results of active searches in India in 1973 (Fig. 4.3), described in detail in Chapter 15, suggested that at that time the reporting efficiencies in the highly endemic states of Madhya Pradesh and Uttar Pradesh were less than 1% and 5% respectively—and this a decade after the launching of the Indian national smallpox eradication programme and 6 years after the initiation of the Intensified Smallpox Eradication Programme. Likewise, with the development of

Fig. 4.3. Evidence of the underreporting of variola major. Increase in the number of reported cases in India following the introduction of active searches in the highly endemic states in 1973 (see also Chapter 15, Fig. 15.15). NSEP = National Smallpox Eradication Programme of India.

Fig. 4.4. Evidence of the underreporting of variola minor. Increase in the number of reported cases in Ethiopia following the initiation of intensified surveillance in 1971.

better surveillance in Ethiopia in 1971 (see Chapter 21), there was a dramatic increase in the number of reported cases, 722 being notified in 1970 and 26 329 in 1971 (Fig. 4.4).

For China, the most populous country in the world, with endemic variola major for centuries and poor vaccination coverage prior to 1950, the cases reported to the international health authorities were in the thousands only, the highest figure (68 101) being reported in 1951, just after the national eradication campaign had been launched.

#### *The overall picture*

It is clear that the reporting of cases of smallpox was the most efficient in countries in which the health services were well developed, which was usually where the disease was least common. It was very inefficient elsewhere. Since the countries in which reporting was good must have provided only a small proportion of the total number of cases in the world, it is not unreasonable to regard the official figures reported to WHO as representing only 1–2% of the true incidence—probably nearer 1% for the years before the initiation of the global eradication programme. In the early 1950s, 150 years after the introduction of vaccination, there were probably some 50 million cases of smallpox in the world each year, a figure which had fallen to perhaps 10–15 million by 1967, when the disease had already been eliminated in 125 of the 156 countries and areas listed in the legend of Fig. 4.1.

### **The Effect of Vaccination on the Incidence of Smallpox**

As has been described in Chapter 1, an attack of smallpox in persons who had been vaccinated was usually less severe than in the unvaccinated. Much more important, from the point of view of the ultimate eradication of smallpox, was the fact that vaccination within the previous 5 years usually completely prevented disease. Some vaccinated persons experienced subclinical infections, as judged by their serological responses (Heiner et al., 1971a). These subjects did not transmit the disease to others, although the subclinical infection substantially increased their level of immunity. Even if their immunity had not been boosted by subclinical infection or revaccination, many vaccinated individuals were protected against clinical smallpox for a much longer period than 5 years. However, no data exist which allow an accurate assessment to be made of the proportion of those at risk who were protected against smallpox at various intervals after vaccination. Such data as are available suggest that vaccination in infancy protected most of those under 10 years of age and at least half of those aged 10–20 years from overt disease.

### **Case-Fatality Rates in Smallpox**

Data from the Indian subcontinent show that Asian variola major had always been a disease with a high case-fatality rate, of the order of 20% or more in unvaccinated persons. Higher case-fatality rates were observed in urban hospitals than in the population as a whole, as documented in Bangladesh (Koplan et al., 1978; see Chapter 1), and in cities than in rural areas (see Table 4.6). Historical documents suggest that high case-fatality rates had prevailed everywhere in the world for many centuries. Indeed, epidemics in previously unexposed, subsistence-farming populations appeared often to have produced much higher mortalities than those seen in Asia, owing to the social disruption and consequent starvation that they caused.

From about the end of the 19th century another variety of smallpox, variola minor, was recognized, which although it produced similar skin lesions had a case-fatality rate of only about 1% (see Chapter 1). Subsequently, observations made in Africa during the Inten-

sified Smallpox Eradication Programme suggested that smallpox of intermediate severity, with case-fatality rates of 5–15%, was endemic in many parts of that continent.

In addition to differences in the virulence of the virus, several other important variables can be identified that played a role in the observed variations in case-fatality rates: the age distribution of cases, the effects of previous vaccination, nutritional status, and the influence of reporting accuracy, since severe (hospitalized) cases and deaths were more likely to be reported than milder cases. Pregnant women were especially susceptible and showed higher case-fatality rates for both variola major and variola minor than did men and non-pregnant women of the corresponding age groups (see Chapter 1). Further, there were interactions between age and vaccination status, since in persons receiving only primary vaccination, susceptibility increased with the interval since vaccination and thus with age. Relevant data from India and from western and central Africa are set out in Tables 4.2 and 4.3.

Foege et al. (1975) noted that the age distribution of cases in western and central Africa in 1968 followed closely the age distribution of the population, reflecting the predominant occurrence of cases in isolated and poorly vaccinated rural areas. In India, on the other hand, with its much denser and more mobile population, smallpox was predominantly a disease of children (over 70% of cases in individuals under the age of 15 years: Table 4.2); the situation was similar in Bangladesh, Burma, Indonesia and Pakistan. Since the immunity produced by vaccination in childhood steadily waned, the majority of cases in vaccinated subjects occurred in older age groups (54.3% in persons over 14 years of age: Table 4.3), whereas in unvaccinated subjects 82.3% of cases occurred in children less than 15 years old. The age-related trends in case-fatality rates were similar in India and Africa, the rates being highest in the very young and in older persons. Children and adolescents (10–19 years of age) had lower case-fatality rates than any other age group, a feature which was accentuated when only

<sup>b</sup> Thought to be cases vaccinated during the incubation period.

unvaccinated subjects were considered. However the data are analysed, the case-fatality rates were higher in India than in western and central Africa. Nevertheless, the age distribution of cases clearly influences the overall case-fatality rate for a particular geographical region, and critical comparisons of geographical variability in case-fatality rates would have to assess separately the figures for vaccinated and unvaccinated subjects and consider the age distribution of cases of smallpox. Unfortunately, there are very few large series of cases, from different geographical areas, that give such details; the analyses that follow are the best available.

Shafa (WHO/SE/72.35) analysed data from 11 areas for which he considered that reasonably reliable information was available, making adjustments for age-specific case-fatality rates by adjusting the data to a standard age distribution. The case-fatality rates for 9 areas in which variola major was endemic are shown in Table 4.4. They were always higher among infants and children aged 0-4 years than among individuals in older age groups.

<sup>b</sup> Includes both vaccinated and unvaccinated subjects.

<sup>c</sup> More recent data (Joarder et al., 1980) suggest that the lower figures (26.8% and 18.5%) represent more accurately the true situation in Bangladesh.

The effect of age on mortality was even more pronounced in variola minor, in both Brazil and Africa, in which the case-fatality rate was much higher for infants (less than 12 months old) than for any other age group (Table 4.5). Indeed, in Brazil, in which data were available for infants less than 3 months old, the case-fatality rate in this group was 16.7%.

Geographical variations in crude case-fatality rates, based on data obtained during the Intensified Smallpox Eradication Programme, are shown in Table 4.6. There are striking differences between the case-fatality rates in large cities and those in the surrounding countryside (see Indonesia and Pakistan). This may have been due partly to the better recording of deaths and partly to the fact that data for the cities were derived in large measure from hospitals, in which more severe and neglected cases were more common (Koplan et al., 1978).

There are also large differences between the case-fatality rates in countries in which variola minor was endemic and those in other countries. Variola minor itself varied in severity, the form present in Botswana in 1972 (which may have been characteristic of "amaas" of southern Africa) being particularly mild. Smallpox other than variola minor was associated with case-fatality rates that varied in different geographical areas from slightly more than 5% to over 20%. There were suggestions in the mid-1960s that strains of virus from eastern African countries (Uganda and the United Republic of Tanzania) could be differentiated from Asian strains of variola major virus by laboratory tests, and it was suggested that the disease there should be called "variola intermedius". However, the "characteristic" laboratory reactions of "variola intermedius" were not invariable for strains from that area, and case-fatality rates only slightly higher than those found in eastern Africa were also recorded for Indone-

sia and western Africa. As has been suggested in Chapters 1 and 2, it is possible to differentiate between variola major and variola minor by considering clinical features and epidemiology and, for some strains, the laboratory characteristics of the virus, but it is not worth while to attempt to designate “variola intermedius” or to differentiate further between strains of variola major. The data shown in Tables 4.4 and 4.6 illustrate the fact that both variola major and variola minor were caused by strains of variola virus which differed in their virulence for man, and that some strains were predominant in some geographical areas and other strains in other areas.

### Smallpox Epidemics in Endemic Countries

It was widely observed that in countries in which smallpox was endemic there were periodic episodes of much higher incidence: “epidemic years”. The history of smallpox before the 20th century is replete with accounts of great epidemics occurring against a background of endemic smallpox (see Chapter 5). An unusually complete series of data on smallpox incidence in the Åland Islands, Finland, extending from 1751 to 1890, showed a 7-year cycle of epidemics in the 18th century, which changed to an 8-year cycle, with a higher proportion of cases among adults, after vaccination became avail-

Fig. 4.5. Cyclic fluctuation in the incidence of smallpox in the city of Madras, India: annual numbers of cases and deaths between 1910 and 1960. (Based on Rao et al., 1960.) A similar cyclic fluctuation, with epidemics every 5–10 years, occurred in India as a whole and most other countries in which smallpox was endemic. (See Chapter 5, Fig. 5.2 and Chapter 6, Fig. 6.1.)

able in 1805 (Mielke et al., 1984). The phenomenon of epidemic years is well illustrated by more recent data from India. In the city of Madras, for example, Rao et al. (1960) found that there was a regular peaking of incidence every 4–6 years, epidemics extending over a period of 3 years, the middle year being the peak year (Fig. 4.5). This periodic

behaviour is a consequence of the size of the pool of susceptible individuals in the population and the rate of their removal by infection or vaccination. The phenomenon occurs in all common infectious diseases in which infection is followed by long-lasting immunity; it has been exhaustively analysed in measles (Bartlett, 1957) and is critically dependent on the rate of addition of new susceptible individuals to the population. A factor which lengthened the interval between epidemics of smallpox was that the occurrence of an epidemic led to greatly increased vaccination rates, because of increased activity by public health officials and increased demand for vaccination by the general public.

### Seasonal Variations in Incidence

Most infectious diseases show characteristic seasonal variations in incidence. In temperate climates, where there are pronounced seasonal differences in temperature, arbovirus infections usually occur in summer, enteroviral infections in summer and autumn, influenza and other infections of the respiratory tract mainly in winter, and measles, chickenpox and mumps mainly in winter and spring. Smallpox showed a seasonal incidence similar to that of measles and chickenpox; it was mainly a disease of winter and spring. For several of these diseases the seasonal variations are blurred in tropical climates, where the seasonal changes in temperature and humidity are often much less marked. However, smallpox showed a response to seasonal effects in many tropical regions; in Bangladesh the seasonality was so pronounced that smallpox was called, in Bengali, *guti bashunto*, the spring rash (Joarder et al., 1980).

The most detailed studies of the seasonality of smallpox were those reported by Sir Leonard Rogers, using mortality figures from British India (Rogers, 1926, 1948) and data on reported cases from England and Wales (Rogers, 1928) and certain parts of Africa (Rogers, 1948). Although many of his data were poor, comprising deaths rather than cases, both being grossly underreported, Rogers' observations of the seasonal incidence of smallpox have been confirmed by the more accurate data on case incidence obtained during the global smallpox eradication campaign.

Fig. 4.6 shows the monthly incidence of reported cases of smallpox in representative

BRITISH MEDICAL JOURNAL

**Plate 4.1.** Sir Leonard Rogers (1868–1962). Distinguished British physician who worked in India for many years and was Professor of Pathology at Calcutta Medical College from 1900 to 1920. Besides making important contributions to many aspects of tropical medicine, he devoted particular attention to a study of seasonal effects on the incidence of smallpox.

countries in the Northern and Southern Hemispheres and in the humid tropics. In Bangladesh the maximum reported incidence was in the period from January to the end of April; in Brazil, in the Southern Hemisphere, the maximum reported incidence occurred in the spring, from August to the end of October, with well-marked minima in September to the end of December and in February to the end of May. The maximum incidence in Indonesia occurred in January but thereafter the monthly incidence showed little variation. Bearing in mind the delays in reporting (see box), the maximum transmission rate probably occurred in December in Bangladesh and in June in Brazil—i.e., during the early winter. Old records for European countries (Low, 1918; Mielke et al., 1984) show that smallpox there was also mainly a winter disease.

Within India, Rogers (1928) observed that the seasonal fluctuation was the least marked and the incidence the most uniform from year to year in the State of Tamil Nadu (formerly Madras), in South India, which experienced little seasonal variation in temperature and humidity; these observations were confirmed for the city of Madras by Rao et al. (1960). Other countries in the tropics, which also

### Interpreting Seasonal Fluctuations in Incidence

The analysis of seasonal factors in smallpox is based on curves of monthly incidence of reported cases or deaths, as illustrated in Fig. 4.6. The extent of reporting may affect such curves in a dramatic way, as illustrated during the "search weeks" in India (see Fig. 4.3) and after the initiation of the Intensified Smallpox Eradication Programme in Ethiopia (see Fig. 4.4). However, if it is assumed that the extent of reporting was reasonably uniform throughout each year, over a period of several years, clearly there were large differences in the incidence of reported cases at different times of the year. It is reasonable to ascribe such seasonal effects on the incidence of smallpox to factors, biological and/or social, that affect transmission. It is necessary, however, to determine the average time-lag between transmission and the recording of cases in the statistics.

As the WHO system reported smallpox cases by date of detection rather than date of occurrence, the observed pattern of disease represents a delay from actual transmission by periods of up to 2 months. Factors contributing to this time-lag include the incubation period, delays in case detection, and delays in reporting. As many outbreaks were not detected until the 2nd, 3rd or 4th generation of transmission, all cases detected on the initial investigation would have been recorded in that week—the week of detection.

experience less pronounced seasonal differences in humidity and rainfall—e.g., Indonesia and Zaire—likewise exhibited much less pronounced seasonal differences in the incidence of smallpox (Fig. 4.6). But where there were clearly distinguishable hot and cool seasons, with high and low absolute humidities respectively, the incidence was always much higher in the cool, dry season. Data on importations of smallpox into Europe during the period 1961–1973 support the findings in the endemic countries (see Chapter 23). There were 3 times as many importations during the months December–May as in the following 6 months, which is explained by the higher incidence of smallpox in the main "exporting" countries in the Indian subcontinent at that time. Further, each case imported during December–May gave rise to an average of 24 subsequent cases (median 4.5), whereas each case imported in the period June–November gave rise to an average of 1.6 cases (median 1.0) (Henderson, 1974).

A variety of factors can be envisaged that could have contributed to the seasonal incidence of smallpox: viability of the virus in an infectious state, social factors and possibly the physiological susceptibility of the host.

#### *Viability of the virus*

Experiments described in Chapter 2 show that the viability of variola and vaccinia

viruses was less prolonged at high than at low temperatures and at high than at low humidities. This was true with virus in scabs (Huq, 1976), on raw cotton (MacCallum & McDonald, 1957) and in an aerosol (Harper, 1961). The correlation of low temperature and humidity with a higher incidence of smallpox was observed in many different countries—e.g., India (Rogers, 1928; Basu et al., 1979), Bangladesh (Joarder et al., 1980), western and central Africa (Foege et al., 1975), Brazil (Morris et al., 1971), the USSR (Low, 1918) and Nyasaland (Malawi) (Rogers, 1948)—suggesting that the effect of environmental conditions on the viability of variola virus was probably an important factor in determining the seasonal incidence of smallpox. In some situations, this physical effect was supplemented and amplified by social events that increased opportunities for transmission during the dry season (see below).

#### *Changes in susceptibility of the host*

Another possibility, often invoked to explain the winter incidence of influenza, is that there may be seasonal changes in individual susceptibility, due perhaps to changes in mucous membrane permeability or to alterations in resistance associated with dietary changes. There is no convincing evidence that such factors were important in smallpox.

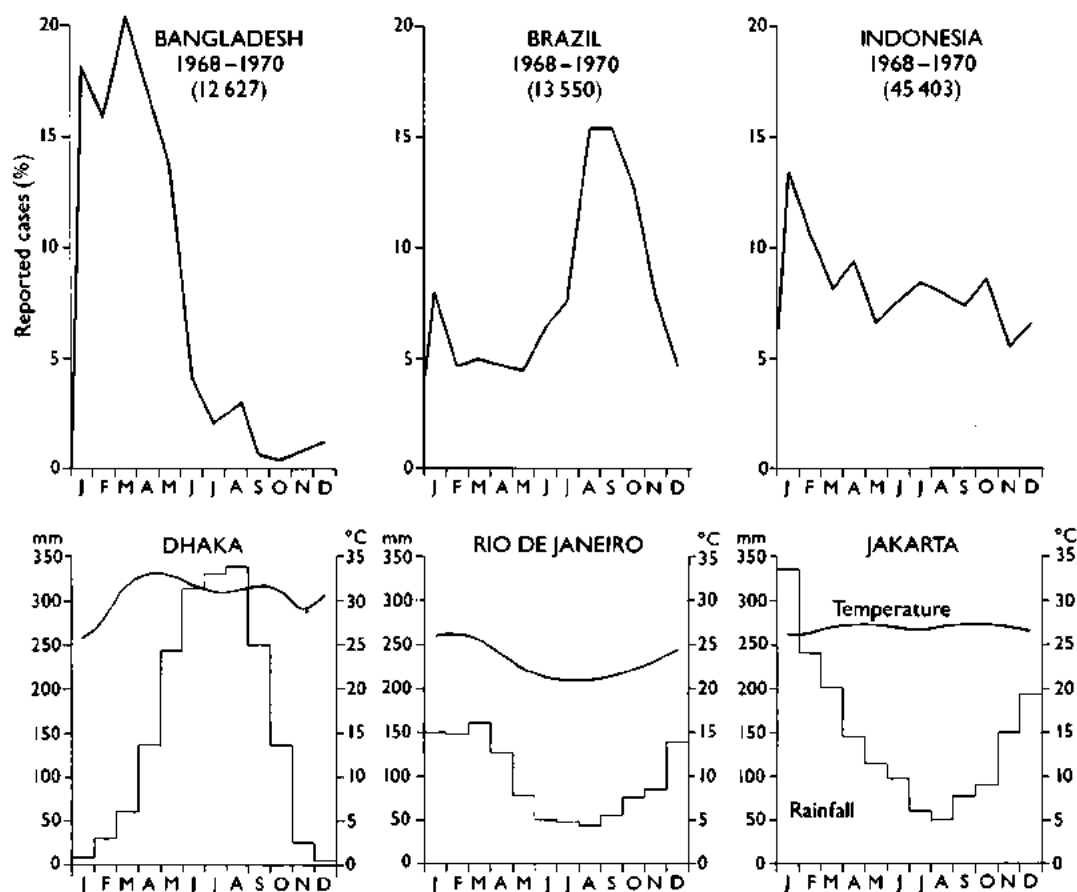

Fig. 4.6. The monthly incidence of reported cases of smallpox in countries situated in the Northern Hemisphere (Bangladesh), mainly in the Southern Hemisphere (Brazil) and in the tropics (Indonesia), as observed during the Intensified Smallpox Eradication Programme. Figures in brackets indicate numbers of cases. The lower graphs show the average monthly rainfall (mm) and maximum temperatures (°C) for Dhaka (Bangladesh), Rio de Janeiro (Brazil) and Jakarta (Indonesia). There was a pronounced seasonal incidence in countries with well-marked wet and dry seasons, but this feature was not as obvious in localities in tropical countries with sustained high humidities, such as Java (Indonesia), or Madras (India).

#### Social factors

Social factors of various kinds amplified the effects of temperature and humidity on the viability of variola virus. In western and central Africa, Foege et al. (1975) observed that the seasonal variation—low in the rainy season (September, October) and reaching a peak in the late dry season (March and April)—was less marked in the humid coastal areas and more pronounced in the dry savanna or Sahel. They suggested that in part, at least, this was due to the effects of climate on social activities. Planting during the rainy seasons resulted in the dispersion of the population in the fields, whereas in the dry seasons there were festivals and many more social contacts in the agricultural areas and the long-distance movement of nomads in the sub-Saharan

areas. These activities facilitated the dissemination of the virus.

In Tamil Nadu (Madras), where the seasonal variation in the incidence of smallpox was not pronounced, Rao (1972) suggested that such variation as was seen was more "man-made" than natural. For example, two population groups belonging to two different communities and professions (Harijans and Gounders) lived very closely together in the same villages, but an outbreak of smallpox was limited to the Gounders (WHO/SE/68.6, Rao). Also, there was greater crowding and, because of the seasonal fluctuation in births, greater numbers of unvaccinated infants in the winter and rainy months, which Rao believed was enough to explain the limited seasonal fluctuation in incidence seen in

### Forecasting Epidemic Years

The prime motive for Roger's studies was to forecast years when smallpox might cause major epidemics. Bearing in mind that seasonal conditions alone were not sufficient to produce epidemics, which could not occur if the pool of susceptible individuals was substantially reduced by recent epidemic prevalence, Rogers (1928, 1948) found a remarkably good association between failure of the monsoon rains and consequently low absolute humidity during the rainy season and epidemic prevalence in the following dry season. Transmission always continued through the rainy season, but there were more chains of transmission when the monsoon rains were poor than with a good monsoon and sustained high humidity. Thus, if the monsoon failed, the population was already extensively seeded with virus when the cooler dry season began, and the stage was set for a major epidemic. Using this criterion, Rogers (1948) found that the great majority of major epidemics could be correctly predicted; most exceptions were satisfactorily explained by the arbitrary nature of his criterion of "epidemic levels". Murthy et al. (1958) noted that in Uttar Pradesh more severe epidemics were likely if an unduly high incidence of smallpox occurred in the post-monsoon months of October and November.

Another factor, on which Rogers did not comment, was that when the monsoon rains were poor, the harvests were also poorer and hunger was more widespread. The extensive movements of refugees and others in search of food led to increased opportunities for the transmission of smallpox.

Madras city. On the other hand, in Pakistan, Mack et al. (1972b) found that there was no seasonal variation in the incidence of transmission within compounds; almost all susceptible subjects were infected when exposed to a case of smallpox, regardless of season. The interval between successive generations of cases was about 3 days longer in the cool season, a result compatible with longer viral survival but not explained by changes in social activity.

#### *Seasonal variation in incidence in relation to eradication*

Whatever its causes, the seasonal variation in the incidence of smallpox was an important factor in the planning of national eradication campaigns. For example, in India before 1973 it had been customary to utilize the end of the monsoons and the beginning of the cool season (September–October), when relatively little transmission occurred and there was no public pressure on health workers to vaccinate, as the leave period for smallpox programme workers. With the intensification of the eradication programme in 1973, rather than merely reacting to the high frequency of disease during the dry season, the policy was changed to concentrate on reducing the foci

of infection during the wet season, when cases were the least numerous. In several countries, the efforts of smallpox workers during the rainy season were concentrated in the urban areas, where smallpox foci were the most numerous. When the rural areas became more accessible at the end of the wet season, efforts were made to eliminate persistent foci of infection during the seasonal lull in transmission.

### INFECTION AND INFECTIVITY

#### Routes of Exit and Entry of Virus

The pathogenesis of smallpox, outlined in Chapter 3, is concerned in the main with how variola virions moved between different cells, organs and tissues within the human body and how the body responded. Epidemiology is concerned with the movement of virus particles between human beings—i.e., with the spread of infection in populations.

There are three principal routes of viral infection, corresponding to the three principal surfaces of the body: the respiratory tract, the alimentary tract, and the skin. Minor routes of infection include the urinary and genital tracts and the conjunctiva. Although congenital infection occasionally occurred in

smallpox (see Chapter 1), it was of no epidemiological importance and will not be discussed further in this chapter.

There is no evidence that infection ever occurred via the alimentary tract in smallpox. In experiments in monkeys, A. R. Rao (personal communication, 1981) fed concentrated suspensions of variola virus in food, or introduced concentrated viral suspensions directly into the stomach with a stomach tube. The monkeys were not infected, nor could virus be recovered from their stools. The latter result may have been due to the fact that variola virus probably behaves like vaccinia virus, which is rapidly inactivated in sewage (K. R. Dumbell, personal communication, 1982).

Mechanical transmission by arthropods is important in some poxvirus infections (myxoma virus in rabbits, fowlpox virus in birds). Sarkar et al. (1973c) showed that mosquitoes could contaminate their probosces with variola virus by feeding on viraemic mice, and they speculated about the relevance of this to human smallpox. Houseflies could and probably did transport variola virus mechanically, especially in tropical countries, but their importance was probably trivial compared with other sources of infection and in any case there is no evidence that the ingestion of virus-contaminated food would produce smallpox. There is no epidemiological evidence to suggest that arthropods of any kind were involved in the transmission of smallpox.

Natural infection in smallpox usually occurred via the oropharynx or nasopharynx, sometimes via the lower respiratory tract, in special cases (inoculation variola and variolation) via the skin, and possibly, but in any case very rarely, via the conjunctiva. Before describing the processes of infection by these routes it is useful to consider how variola virions were shed from the infected patient and entered the environment and the way in which their mode of exit from the patient may have influenced their infectivity for man.

### Shedding of Variola Virus

As we have shown in Chapters 1 and 3, after an incubation period of 12–14 days during which there was no evidence of viral shedding, lesions developed in the skin and the mucous membranes of the nose and mouth.

### *Oral, nasal and pharyngeal secretions*

Because there is no tough stratum corneum in the mouth and pharynx, the lesions there ulcerated very soon after their formation (see Chapter 3, Plate 3.7) and released large amounts of virus into the oral and pharyngeal secretions. Several reports are available on the viral content of oropharyngeal secretions in variola major, all carried out with material obtained from cases occurring in the Indian subcontinent (Madras: Downie et al., 1961a; Calcutta: Sarkar et al., 1973a; Bihar: Kitamura et al., 1977b; Karachi: Shelukhina et al., 1973). Table 4.7 sets out the results of the two most extensive studies. The higher proportion of positive results recorded by Sarkar et al. (1973a) probably reflects the different modes of collection of the specimens in the two studies: throat swabs in Sarkar's series (of which the whole extract in 1 ml of fluid was assayed) and 5 ml of mouth washings (of which only 0.2 ml or 0.3 ml was assayed) in Downie's series. Besides the volumetric differences, throat swabs could be expected to detach virus particles from superficial lesions as well as including those free in the saliva. Both groups of investigators recorded positive results throughout the period of rash (3rd–14th days).

The results of titrations carried out by Sarkar et al. (1973a), shown in a condensed

form in Table 4.8, reflect the high viral content of the oropharyngeal secretions during the first week. The viral titres reached their highest level on the 3rd and 4th days of the disease (i.e., just after the appearance of the rash); they were highest and persisted for the longest period in the most severe cases (confluent, which in Sarkar's terminology included confluent ordinary-type and flat-type smallpox). In fatal cases virus was usually still present in the throat swabs at the time of death; in non-fatal cases it was found for as long as the 14th day from the onset of fever in

confluent ordinary-type smallpox and until the 7th-9th days in discrete ordinary-type smallpox.

#### Skin lesions

The titres of virus in vesicular fluid and in scabs were assayed by Mitra et al. (1974) and Kitamura et al. (1977b). On about the 18th day of the disease (15th or 16th day of rash) the skin lesions scabbed and subsequently the scabs separated. Assay of the viral content of such scabs revealed that they contained a large

amount of virus and that the viral titre, as assayed by extracting the scabs in saline, remained at a high level throughout convalescence (Mitra et al., 1974).

Epidemiological observations, described below, abundantly confirmed the higher frequency of infection after face-to-face contact with a patient during the 1st week of rash. Exposure to patients in the late stages of the disease, when large amounts of virus were being released into the environment in the scabs, was much less likely to produce infection in susceptible contacts. The reasons for this difference in frequency of transmission were difficult to study experimentally. Oropharyngeal secretions expelled early and scabs released late in the disease contained virions that were equally infectious by ordinary assay methods, which involved suspending material from swabs in saline, or homogenizing the scabs by grinding, and assaying the suspension or the homogenate on the chorio-allantoic membrane or in cultured cells. Perhaps the main reason for the differences observed lay in the physical state of viral particles shed by the patient from the enanthem and in scabs.

Virions released from lesions of the enanthem into the oropharyngeal secretions in the early stages of the rash were expelled by the patient in liquid droplets of various sizes, which might be inhaled by persons in close contact with the patient or transferred directly to the nose or oropharynx by fingers or objects contaminated with infected saliva or nasal secretions (Knight, 1973; Gwaltney & Hendley, 1978). Many of the large droplets would rapidly fall and dry on the bedclothes or the floor, being readily dispersed again in the immediate vicinity of the patient. Virions transferred in these ways would readily come into contact with susceptible cells. In hospitals in non-endemic countries, nurses who made up the beds of patients suffering from undiagnosed smallpox were often infected; others were protected by vaccination but developed "smallpox-handler's lung" due to the inhalation of virus.

In contrast, virions in scabs were enclosed within the inspissated pustular fluid and were present in flakes which contaminated the patient's skin and bed-linen and the dust on the bed and the floor of the room. It is likely that virions in scabs would rarely have come into direct contact with susceptible cells, since inspired particulate matter of this kind is usually swept up in the mucous secretions of

the oropharynx and swallowed, or expelled again into the environment. However, such virions could retain infectivity for long periods, as judged by laboratory assay.

In spite of this virological evidence, the policy of isolating patients adopted during the Intensified Smallpox Eradication Programme followed that traditionally taught—i.e., patients were not removed from isolation in hospital or at home until the last scab had separated. As smallpox eradication became imminent in Bangladesh and India, villages were considered to house infective persons for 6 weeks after the onset of the last recognized case. This policy of isolation and surveillance provided a safety margin, since sometimes infants or other persons became infected and were hidden from surveillance officers, thus constituting a missed generation of cases.

Several studies have been made of the presence of variola virions in the air and on fabrics and skin in the vicinity of smallpox patients. In evaluating these reports it must be borne in mind that the ventilation rate of adult human beings is about 10 litres per minute, so that the air-sampling device would have had to test a volume of about 600 litres in order to be comparable to an hour's exposure of a susceptible adult person. Unfortunately, rather inefficient methods of air sampling were used in the earlier studies. Using small glass funnels tightly packed with dry cotton wool through which air was drawn, Meiklejohn et al. (1961) obtained only one positive result in the wards of the Infectious Diseases Hospital in Madras. Subsequently, Downie et al. (1965a) analysed the immediate environment of smallpox cases in the same hospital using three devices: (1) a fluid impinger which excluded particles of 18  $\mu$ m or more in diameter, held near the patient's mouth for periods of 10–15 minutes that included talking and coughing; (2) settling-plates placed below air samplers; and (3) swabbing of skin and bedclothes. The results, summarized in Table 4.9, show that virus was rarely found in the small airborne droplets or droplet nuclei, although the saliva and the patient's pillow covering were heavily contaminated.

Westwood et al. (1966) studied the problem experimentally by assaying the air in the environment of rabbits infected with rabbitpox virus with sampling devices similar to those used by Downie et al. They recorded some positive results, but sampling was often negative at times when the rabbits were clearly infectious. Thomas (1970a) repeated

<sup>a</sup> Based on Downie et al. (1965a).

these experiments using a slit sampler (Andersen, 1958; Thomas, 1970b) that sampled a larger volume of air and did not discriminate against the collection of larger particles from a heterogeneous aerosol, as did the fluid impinger and electrostatic precipitator. As might be expected, he obtained more frequent positive results and recorded higher titres of virus than the earlier workers. Subsequently Thomas (1974) compared impingers and sedimentation plates of the type used by Downie et al. (1965a) and a slit sampler like that used in his rabbitpox experiments in the sampling of the air in a hospital in England. His subjects were a few patients in a ward who were recovering from variola minor, a situation in which much less environmental contamination with virions would have been expected than in the Infectious Diseases Hospital in Madras. The impingers gave uniformly negative results, but virus was detected with the slit sampler in air near the bed on several occasions, associated with the physical activity of patients with active lesions. Sedimentation plates exposed for some hours about 20 feet from the occupied beds also yielded virus on several occasions.

An important feature of smallpox in relation to long-distance airborne spread was that patients with uncomplicated smallpox usually had no respiratory signs or symptoms; coughing and sneezing, which generate large clouds of infective aerosols in the acute stages of measles, for example, rarely occurred. When they did, as in the index cases in the Monschau and Meschede Hospital outbreaks (Anders & Posch, 1962; Wehrle et al., 1970; see later in this chapter) airborne infection within buildings could occur.

## Urine

The urine was examined for variola virus by Downie et al. (1965a) and Sarkar et al. (1973a), with the results shown in Table 4.7. Sarkar et al. recorded the titre of virus in cases which at some time had viruria (21 out of the 39 cases examined). The titre was highest early in the disease (days 5 and 6); it was higher and more persistent in severe cases (haemorrhagic smallpox and those with a confluent rash) than in milder cases. No virus was detected in the urine of some cases whose severity was comparable to that of cases with viruria. Shelukhina et al. (1973) reported that a few patients excreted small amounts of virus in the urine during convalescence (23rd and 25th days of the disease). However, both because of the small quantities of virus involved and because of the mode of excretion, it is unlikely that urine was an important source of infectious virus.

## Routes of Infection

Variola virus usually gained entrance to the body via the oropharynx or respiratory tract, and occasionally through the skin, usually by direct inoculation, as practised in variolation.

### Entry via the respiratory tract

Particles enter the nose or mouth, other than in food or drink, either by inhalation, or by implantation on the oral or nasal mucous membrane by contact with contaminated fingers. A great deal of experimental work has been carried out on the fate of inhaled bacteria and viruses (reviewed in *Bacteriological reviews*, 1966; Gregory & Monteith, 1967; Hers & Winkler, 1973). Some relevant aspects can be summarized as follows. The ventilation rate of an adult human being is about 10 litres per minute. Most particles larger than 15  $\mu\text{m}$  in diameter and about half those 6  $\mu\text{m}$  in diameter are retained in the nose. Large particles deposited in the nasal cavity or oropharynx are usually carried to the back of the throat and swallowed. Particles deposited in the lower respiratory tract may be trapped in the mucus and borne upwards from the lungs to the back of the throat by ciliary action. However, smaller particles may reach the lungs, those 1  $\mu\text{m}$  or less in diameter reaching the alveoli, where they may cause

infection of cells of the alveolar walls, or alveolar macrophages.

Size and physical state are also important in determining whether expelled particles fall quickly to the ground or remain airborne for a long time. Large particles—particularly scabs—fall quickly to the ground. Smaller liquid particles dry rapidly and float for a long time in the air, thus increasing the chance that they may enter the respiratory tract. The vigorous shaking of heavily contaminated bed-linen may disperse clouds of small particles of infected "dust" in the air (Duguid & Wallace, 1948).

The other critical factor in determining the infectivity of both large- and small-particle aerosols generated by talking, coughing and sneezing is the concentration of virus in the secretions of the nose and mouth. Experiments with bacteria showed that many of the expelled particles were sterile unless the concentration of bacteria in the secretions reached  $10^6$  per ml or more (Duguid, 1946).

Organizations that some years ago were concerned with research on biological warfare carried out a great deal of work on respiratory infection with viruses, including orthopoxviruses; some investigations of this kind have also been conducted in other laboratories (Noble & Rich, 1969). Relevant publications on the subject deal with two systems: rabbitpox virus in rabbits (Westwood et al., 1966; Lancaster et al., 1966; Thomas, 1970a) and variola virus in monkeys (Hahon & McGavran, 1961; Noble & Rich, 1969). These experiments were described in more detail in Chapter 3; their importance in the present context is the demonstration that susceptible laboratory animals can be readily infected by aerosols of orthopoxviruses. However, neither in smallpox nor in the experimental infection of animals with orthopoxviruses has evidence of a primary lesion been found in either the oropharynx or the lower respiratory tract; it seems likely that infection could occur at any site from the nasal mucosa to the alveoli, but that no "local lesion" developed.

#### *Inoculation through the skin*

For the genus *Orthopoxvirus* as a whole, the skin is a relatively common portal of entry, usually through breaches in the surface, which may be minute. It is the usual portal of entry of ectromelia virus in mice (Fenner, 1947b), as well as the common route of

infection with cowpox virus in both cows and humans, and was deliberately used for inducing vaccinia infection in man—i.e., vaccination against smallpox. Infection through the skin with variola virus occupied a special position in the history of smallpox. Accidental inoculation with variola virus occurred in certain occupational groups—e.g., among hospital personnel or mortuary attendants dealing with unrecognized smallpox. However, a much more common situation for centuries in India and China, during the 18th century in Europe, and up to recent times in some parts of Asia and Africa (see Chapters 6, 14 and 21), was the practice of variolation, or "inoculation" as it was called before the introduction of vaccination (Miller, 1957). In China a "snuff" of dust containing variola virus was originally used, but in other countries, and in China since the early 19th century, the virus was introduced into the skin.

Inoculation smallpox showed important differences in pathogenesis and symptoms from smallpox acquired by the respiratory route (see Chapters 1, 3 and 6). In the case of the former, there was always a local lesion at the inoculation site; "daughter pustules" often developed in the skin near the inoculation site; the generalized rash appeared two or three days earlier and the course of the disease was usually much less severe than in naturally transmitted smallpox. However, oropharyngeal lesions occurred as part of the generalized disease and these lesions, in particular, constituted sources of infection of contacts.

#### **The Infectious Dose of Variola Virus**

During the 1940s and 1950s substantial experimental work was undertaken to determine the number of particles of vaccinia virus needed to infect selected cells or animals by various routes of inoculation. It was found that for a highly susceptible animal or cell system, a single viable virus particle could initiate infection (Parker, 1938), although usually the ratio of particles to "takes" was much more than 1 to 1 (Sharp, 1965). In contrast, in man a relatively high concentration of vaccinia virus was needed to produce consistently successful primary vaccination takes. It was recognized that only a very small proportion of the virus in the inoculum was actually introduced into the epithelium by scarification or multiple puncture vacci-

nation. However, in assays by scarification, the 50% infectious dose was found to be  $3 \times 10^5$  pock-forming units per ml for the Lister strain (Cockburn et al., 1957) and about  $10^7$  pock-forming units per ml for the attenuated CVI strain (Cherry et al., 1977).

Man was the natural host of variola virus, and *a priori* it might be expected that a single viable virus particle, lodged in an appropriate site, could be infectious, although because of non-specific protective mechanisms a larger dose would usually be required. However, assays could obviously not be carried out and this must remain a supposition based on analogy with vaccinia virus in highly susceptible hosts.

The form in which the infectious virus was presented to susceptible cells was a more important factor than the actual viral content in determining whether virus in various excretions or secretions would cause infection. For example, when variola virions were present in fresh oropharyngeal secretions, there was a high probability that unvaccinated subjects, exposed by inhalation or direct contact, would be infected. On the other hand, much larger amounts of infectious virus (as judged by laboratory assay of scab extracts) enclosed within inspissated pus in scabs usually failed to produce infection. Such fragments were handled as foreign bodies by the mucociliary cleansing apparatus of the respiratory tract and excreted or swallowed, without causing infection.

### The Incubation Period of Smallpox

It was difficult to measure the incubation period accurately in situations in which smallpox was endemic, for exposure usually occurred over a period of several days. However, precise observations were possible in importations of smallpox into Europe. Downie (SE/72.3) summarized data from 16 outbreaks of variola major and 2 outbreaks of variola minor, occurring in several European countries between 1927 and 1960 and involving 898 cases. Among these the exact incubation period (from a single exposure up to the 1st day of fever) could be determined in 83 cases. Mack (1972) investigated 49 importations of smallpox into Europe over the period 1950–1971 and published histograms of the incubation periods (to the onset of symptoms) for individuals whose possible exposures extended over 1, 2 or 3 days. Subsequent to these

Fig. 4.7. The incubation period of variola major and variola minor, from day of exposure to the onset of symptoms. (Based on data from SE/72.3, Downie; Mack, 1972; and WHO/SE/73.57, Litvinjenko et al.)

analyses, the 1972 epidemic in Yugoslavia (WHO/SE/73.57, Litvinjenko et al.; Stojkovic et al., 1974) provided data for the calculation of the incubation period in 171 persons with variola major. Fig. 4.7 is a histogram based on the information provided by Mack for 1-day exposures in outbreaks occurring over the period 1950–1971, on Downie's data prior to 1950, and on data from the Yugoslav outbreak. In all cases the incubation period was taken as the interval between exposure and the onset of symptoms, rather than the time of appearance of the rash, which was usually 2–3 days later.

These precise data support the widely expressed opinion that the incubation period was usually 10–14 days but, in rare instances, as short as 7 or as long as 19 days. Downie concurred with the observation that acute fulminating cases of smallpox, especially haemorrhagic-type smallpox, may have had a shorter incubation period than the average, but he did not believe that previously vaccinated individuals had unusually long incubation periods, as some writers have suggested.

Variola minor appeared to have had essentially the same incubation period as variola major.

The incubation period in inoculation variola (variolation) was about 2 days shorter than in contact infection—i.e., 8 or 9 days to the onset of fever; or 5 days if the production of a local skin lesion at the inoculation site was taken as the first sign of disease (Dimsdale, 1767).

### The Infectivity of Cases of Smallpox

Smallpox patients, especially those with a severe rash and enanthem, were surrounded by their infected oropharyngeal secretions and later by scabs, both of which contaminated their skin, bedclothes and to a lesser extent the air in their immediate vicinity. Susceptible individuals could be infected by coming into direct contact with the patient and his contaminated bedclothes or by inhaling infective droplets; or, more distantly, laundry workers could sometimes be infected after handling contaminated bed-linen. Very rarely, longer-range airborne infection occurred, when the contaminated droplets originating in the mouth and pharynx were smaller and more numerous, because the patient coughed or sneezed, and air currents transported infective droplet nuclei away from the immediate vicinity of the patient.

#### *Period of infectivity*

The maximum infectivity of cases of smallpox was during the 1st week of rash, corresponding to the period when the lesions of the enanthem had ulcerated and were releasing virus into the secretions of the mouth and pharynx (see Table 4.8). At this stage the skin lesions were intact; the large amounts of virus later shed from the skin were not highly infectious because of the physical state of the virus particles, enclosed within hard dry scabs. For example, Mack (1972) found that the vast majority of cases infected after contact with cases of smallpox who had arrived in Europe from endemic countries while incubating the disease occurred within 3 weeks of the initial time of exposure (Fig. 4.8). In the hospital environment, the mean interval between the point at which a case first became infectious and the onset of symptoms in contacts was in the same range as estimates of the incubation period. In households, transmission took place a few days later, but in both situations the great majority of cases appeared within 3 weeks of the initial exposure.

It was difficult to obtain evidence of the infectivity of patients during the latter part of the incubation period or during the pre-eruptive fever; one series of assays of the oropharyngeal secretions of case contacts (see below) suggested that occasionally virus was present before the eruptive stage. However, epidemiological experience suggested that transmission very rarely occurred before the

Fig. 4.8. The interval between the first possible exposure to a case of smallpox imported into Europe by air and the onset of symptoms in first generation indigenous cases, in family and hospital environments. (Based on Mack, 1972.)

1st day of rash. For example, in rural Pakistan Mack et al. (1972b) found no evidence of significant transmission during the prodromal period. Theoretically, cases remained infectious until the last scab had separated (usually from the soles of the feet) but the level of infectivity fell off greatly as the lesions of the enanthem healed during the latter part of the 2nd week of the disease.

#### *The relative infectivity of different clinical types of smallpox*

Two distinct variables were involved in determining the relative infectiousness of different cases of smallpox: the quantity of virus excreted in the oropharyngeal secretions and the number and extent of the face-to-face contacts between the patient and susceptible persons, especially during the period when large quantities of virus were being excreted. Cases with a severe rash and enanthem were more infectious than those with a slight rash and enanthem, which was why most cases of modified-type smallpox were not highly infectious. However, cases with early severe toxæmia—that is, most cases of variola major in unvaccinated persons—were usually confined to bed during the prodromal stage and were thus segregated from the community. On the other hand, although patients with modified-type variola major excreted less virus, they often moved about the community relatively freely and were thus in contact with

Table 4.10 Frequency of transmission of smallpox to household contacts in villages in Pakistan by cases occurring in unvaccinated and vaccinated subjects<sup>a</sup>

Status of index case	All contacts			Vaccinated contacts		
	Number	Contracted smallpox	%	Number	Contracted smallpox	%
Unvaccinated	390	83	21.3	271	15	5.5
Vaccinated	52	3	5.8	48	1	2.1

<sup>a</sup> Based on Heiner et al. (1971b).

many more persons. Such cases were frequently blamed for importations into the United Kingdom in the period after the Second World War, and in the 1972 outbreak in Yugoslavia 2 mild ambulant cases, not recognized as smallpox, generated 11 and 16 secondary cases respectively (Stojkovic et al., 1974). In general, however, persons who were infected despite previous vaccination were only one-fourth as likely as unvaccinated cases to transmit infection to household contacts (Table 4.10).

Rao (1972) found that the most highly infectious cases in Madras were those of ordinary- and flat-type smallpox in unvaccinated subjects. Studies in rural Bangladesh (Thomas et al., 1971b) showed that patients who died had been more infectious to family contacts during their illness than those who survived, and in rural Pakistan Mack et al. (1972b) found that while almost all susceptible persons within the relatively confined environment of compounds were infected, regardless of the severity of the index case, spread between compounds was much greater if the index case was severe.

Because the toxæmia was so much less in variola minor, cases often remained ambulatory during their period of highest infectivity and were thus likely to spread smallpox in the community, a feature which partially explains the persistence of endemic variola minor in Brazil, Great Britain and the USA after variola major had been eliminated from those countries.

#### *Absence of recurrent infectivity*

Another important epidemiological feature of smallpox was that recovery from an acute attack was followed by elimination of the virus; recurrence, with excretion of virus, never occurred (see Chapter 3). The epidemiological importance of this aspect of the pathogenesis, in relation to eradication of the disease, can be judged by comparing this situation with the recurrent infectivity found

in varicella-zoster and herpes simplex infections, which accounts for the survival of these diseases in remote and isolated populations (Black et al., 1974).

#### **The Infectivity of Case Contacts not Exhibiting Disease**

Epidemiological observations before and during the eradication programme gave rise to a widely held belief that subclinical cases, patients still incubating the disease, and contacts of cases did not constitute important sources of infection. Although infection was sometimes associated with handling inanimate objects (fomites) and, rarely, seemed to be airborne over a considerable distance (see below), the vast majority of cases of smallpox could be traced to face-to-face contact of a susceptible person with a patient with overt disease, usually during the 1st week of rash. However, careful laboratory studies by Sarkar et al. (1973b, 1974) showed that about 10% of household contacts of cases of smallpox harboured detectable amounts of variola virus in their oropharyngeal secretions. Only about 10% of such carriers subsequently developed smallpox. These authors cautioned against too ready an acceptance of the view that asymptomatic carriers were not a significant factor in the epidemiology of smallpox.

Looking at the situation after smallpox has been eradicated, it seems probable that infection might occasionally have occurred from case contacts or those incubating the disease. Such events might have been responsible for what appeared to be abnormally long or short incubation periods. Nevertheless, the opinion of epidemiologists engaged in the global eradication campaign is that the vast majority of cases could be traced to close contact with a patient with an overt smallpox rash; had it been otherwise eradication of the disease from populous countries such as Bangladesh and India would have been much more difficult than proved to be the case.

### Use of the Word "Contact" in Epidemiology

To clarify the discussion which follows it is useful to review the definitions used by epidemiologists for infection via the oropharynx or respiratory tract. Different conventions exist in different countries. In some countries the word "contact" is used only where true physical contact has occurred. In most English-speaking countries the word is used more broadly (Langmuir, 1973), and this was the common usage by epidemiologists engaged in the Intensified Smallpox Eradication Programme. According to this convention, infection which occurs only or mainly at short range, owing to the implantation of infectious droplets expelled from the mouth or nose of the patient during talking, coughing or sneezing, is said to occur by contact, even though physical contact does not occur. Thus "contact" includes physical contact either direct or via the fingers, as well as the direct implantation of large-particle aerosols on the oral, nasal or pharyngeal mucosae or the inhalation of small particles into the alveoli, as long as the infector and infected are in face-to-face contact.

If infection occurs at longer ranges, between persons not in sight of each other, it is regarded as being caused by airborne "droplet nuclei"—the dried particles that result from the evaporation of water from droplets that remain suspended in the air for a period. This is called "airborne infection".

However, the most common use of the word "contact" in this book is to signify a person who has been exposed to the risk of infection with smallpox, whether as a member of a household with an infected case, as a casual visitor to a hospital ward or as a co-traveller in an aeroplane, bus or train.

### TRANSMISSION

The shedding of virus from an infected subject and its transfer to a susceptible person together constitute the transmission of smallpox. Transmission was ordinarily direct, by the implantation of infective droplets on to the nasal, oral or pharyngeal mucous membrane, or the alveoli of the lung, or less commonly indirect, as an airborne infection or from fomites.

#### Contact Infection

Contact infection could result from the inhalation of either large-particle aerosol droplets or droplet nuclei at close range or from transfer via the fingers or various objects.

Epidemiologically, the important question was the relative frequency of infection of very close contacts of the patient and infection, by aerosol, at short distances, such as occurs in tuberculosis (e.g., schoolroom epidemics) and influenza. Comparison of the intrafamilial and extrafamilial spread of smallpox (e.g., Rao et al., 1968a; Thomas et al., 1971a,b, 1972) demonstrated that the overwhelming ma-

jority of secondary infections occurred in close family contacts of overt cases of smallpox, especially in those who slept in the same room or the same bed. Next in frequency were those who lived in the same house; residents of other houses, even in the same compound (who would often have visited the house of the patient), were much less likely to become infected.

Negative evidence was also important. Especially in India, long-distance movements by train or bus of patients suffering from smallpox, with an overt rash, used to occur frequently, yet infection of casual fellow-travellers was rare indeed—so rare that instances of it were deemed worthy of special report (e.g., WHO/SE/72.41, Suleimanov & Mandokhel).

#### Indirect Transmission

Rather than being propelled direct from the patient on to the oropharynx or nasal mucosa of a susceptible contact or transferred by contaminated fingers or various objects (contact infection), infective particles may reach the same sites by indirect routes, after travelling considerable distances either in the

air or on fomites. Because experience had shown that most patients had been infected by face-to-face contact, indirect transmission was implicated only after all possibilities of such contacts had been eliminated.

#### *Airborne infection*

There is good epidemiological evidence that some viral infections, usually those associated with coughing and sneezing, are spread by aerosol over short distances (Coxsackievirus disease: Couch et al., 1970; influenza), while a few, notably foot-and-mouth disease, may be spread by the wind over distances of several kilometres (Donaldson, 1979; Gloster et al., 1982). Towards the end of the 19th century there was a great controversy in Great Britain about the siting of smallpox hospitals, based on the view propounded by some (e.g., Power, 1886; Buchanan, 1905) that infection could be carried by aerial spread for considerable distances from such hospitals. Collie (1912) and Dixon (1962), in reviewing the evidence, pointed out the difficulty of proving the occurrence of this type of spread in situations in which smallpox was endemic or not under control; mechanisms other than aerial spread could have been responsible in most instances. However, Christie (1980) describes a particular case which he claims is best explained by aerial spread from a hospital situated 400 yards (about 365 metres) away.

In India also it was sometimes said that the hospital was the focus from which the wind-borne spread of smallpox occurred. Hospitals were usually located in densely populated areas inhabited by persons of low income, whose vaccination status was often poor. Careful investigation showed that outbreaks of smallpox in these communities were associated with importations from outside the area—e.g., from distant construction sites—and not with spread from the hospital. In Madras, A. R. Rao (personal communication, 1981) noted that the hospital was surrounded by a zone relatively free of smallpox, probably because of more efficient vaccination in that locality. Further, Rao (1972) noted that, although wards for infectious diseases other than smallpox and corridors used by patients with such diseases were located within a few feet of the smallpox wards of the Madras Infectious Diseases Hospital, only 7 cases of smallpox presumably infected in the hospital occurred among 130 000 non-smallpox patients over the 10 years 1959–1968.

Nevertheless, airborne infection over short distances did sometimes occur. Two hospital outbreaks in the Federal Republic of Germany, at Monschau (Anders & Posch, 1962) and Meschede (Wehrle et al., 1970), seem certainly to have been airborne. In the Meschede outbreak an electrician who had just flown back to the Federal Republic of Germany from Karachi, Pakistan, and who, it transpired, had never been successfully vaccinated, was admitted 10 days later to the isolation ward of a large general hospital with a feverish illness that was suspected to be typhoid fever. He was confined to his room, and 3 days after admission developed a rash. Smallpox was confirmed by electron microscopy 2 days later and the patient was then transferred to the smallpox hospital. In spite of rigorous isolation of the patient (because of the suspicion of typhoid fever) and, after smallpox was suspected, the vaccination of all patients and nurses in the general hospital (in several cases with inactivated vaccine), or inoculation with vaccinia-immune globulin, 19 further cases of smallpox occurred there, on all three floors of the building in which the index case had been nursed. The dates of onset of these cases are shown in Fig. 4.9A. Seventeen cases occurred within one incubation period, counting from the 3 days during which the index case was in the hospital and infectious; the last 2 were room contacts of earlier cases, as indicated. The locations of these patients within the hospital are given in Fig. 4.9B, which also shows the results of tests on the carriage of smoke through the hospital. A number of circumstances favoured the airborne transmission of variola virus in this episode:

- (1) the index patient had a densely confluent rash and severe bronchitis and cough;
- (2) the relative humidity in the hospital was very low, a situation that promotes the survival of vaccinia virus (Harper, 1961) and presumably therefore of variola virus; and
- (3) the design of the hospital led to the raising of strong air currents when the building was heated, as it was during the winter, when the episode occurred.

A visitor to the hospital during the period in question (Case No. 8) spent only 15 minutes inside the hospital, away from the patient care areas and the isolation unit corridor, but he nevertheless developed smallpox with onset of fever 11 days after this visit. Case No. 15 was a nurse who was located on the top floor;

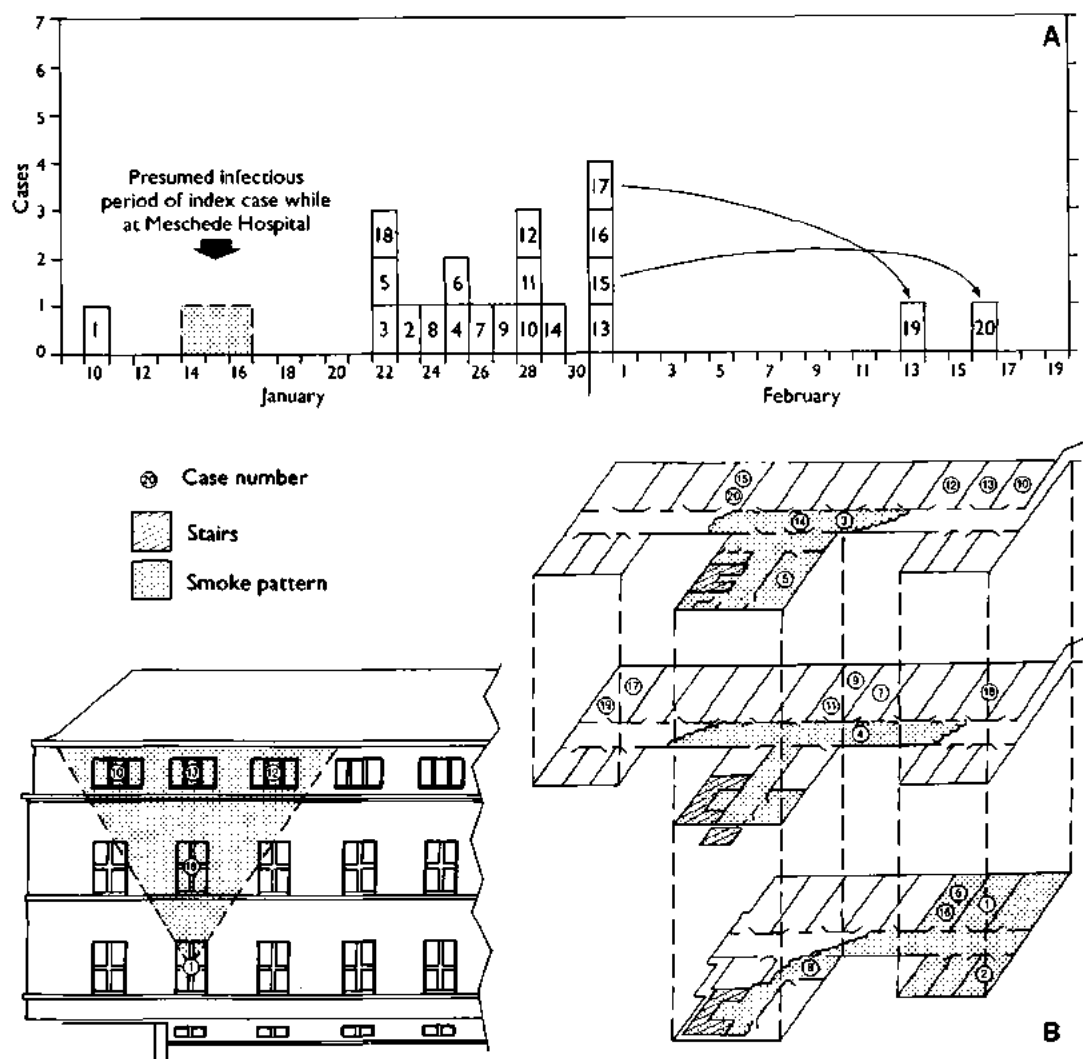

Fig. 4.9. Airborne spread of smallpox in the Meschede Hospital, Federal Republic of Germany, in 1970. **A:** Sequence of infections. The numbers in the histogram indicate case numbers, representing patients who were located as shown below. No. 1 was the index case, No. 8 was a visitor who had spent no more than 15 minutes in a ground-floor office, and No. 19 and 20 were second generation cases who had been in contact with No. 17 and 15 respectively. **B:** Floor plan and rear elevation of the hospital building, showing the location of all cases of smallpox. The shaded area indicates the movement of a cloud of smoke generated in the room in which the patient who was the index case (No. 1) had been nursed before being recognized as having smallpox. (Based on Wehrle et al., 1970.)

she had not left her sick-room while the index case was in hospital nor had she been in contact with persons other than those involved with her case, but she contracted the disease, which manifested itself after an incubation period of about 16 days. Case No. 20 was infected after contact with this patient.

There is no reason to doubt that airborne infection, sometimes over considerable distances, did occur, but it appears to have been

very rare. Short-range aerosol infection was probably responsible for most non-familial cases apparently infected in hospitals, buses and trains. Many laboratory manipulations, such as blending, centrifugation and pipetting, can generate substantial clouds of aerosols; airborne infection from a laboratory is suspected to have been the cause of the last outbreak of smallpox in the world, in Birmingham, England, in August–September 1978 (Shooter, 1980; see Chapter 23).

*Infection via fomites*

The clothing and bed-linen of cases of smallpox were heavily contaminated with virus derived from oropharyngeal secretions and later from ulcerated pustules or scabs (see Table 4.9). Such objects sometimes served as a secondary source of infectious virus for case contacts. There are several documented instances of the infection of laundry personnel whose work-places were located at some distance from the homes or hospitals in which smallpox patients had been nursed, and of chambermaids in hotels (Stallybrass, 1931). Dixon (1962) has summarized reports on infection via fomites and commented that for laundry workers the risk of infection was greatest among those who sorted the incoming laundry and could thus inhale contaminated dust; once wetted the garments and bed-linen were not infectious.

Rao (WHO/SE/72.40) carried out experiments on the persistence of infectivity of variola virus on various objects that had been deliberately contaminated. The most important finding was that, in Madras, virus on such objects was rapidly inactivated, even when they were heavily contaminated; he concluded that fomites were of little importance in the transmission of smallpox in India. In temperate climates virus in scabs could survive on fomites such as cotton for long periods of time (MacCallum & McDonald, 1957); however, virus in scabs rarely appears to have been a source of infection.

As might be expected, the corpse of a fatal case of smallpox and the associated clothing remained heavily contaminated, and smallpox sometimes occurred as an occupational disease among pathologists and mortuary attendants, particularly from unrecognized cases of haemorrhagic smallpox (Dixon, 1962). In endemic countries cases were sometimes associated with funerals (Hopkins et al., 1971c), but these could have been due to exposure by contact with unrecognized cases as often as to infection from the corpse or clothing. From time to time other fomites, such as letters, have been suspected, but incriminating evidence was hard to obtain and the subject is of historical interest only; Dixon (1962) provides a summary.

Another purported association of smallpox with infection from inanimate objects is mentioned only to be dismissed. This relates to folklore in several parts of Africa and India which held that European missionaries who

c. 1970

**Plate 4.3.** Cyril W. Dixon (b. 1912). Worked in the Department of Preventive Medicine at the University of Leeds, England, in 1947–1959, and was Professor of Preventive and Social Medicine at the University of Otago, New Zealand, from 1959 to 1977. He was the author of the standard textbook on smallpox in the English language, which was published in 1962.

occupied a house in which smallpox had occurred months or years before sometimes contracted the disease, supposedly because of residence in that house. However, in such endemic areas there were always opportunities for infection by contact with active cases of smallpox. During the Intensified Smallpox Eradication Programme repeated efforts were made to investigate such stories, but no instances were found in which infection appeared to have been caused by residence in a "contaminated" house.

## FACTORS AFFECTING THE SPREAD OF SMALLPOX

### Individual Susceptibility

In the absence of immunity due to vaccination or other prior infection with an orthopoxvirus, human beings appeared to be uni-

versally susceptible to infection with variola virus. By far the most important factor affecting individual susceptibility was the immunity provided by vaccination. Individual susceptibility to the effects of infection in unvaccinated subjects was influenced by genetic factors and physiological factors such as age and pregnancy. The risk and severity of exposure was influenced by certain occupational factors.

#### *Genetic factors*

Although racial differences in susceptibility probably did exist, they were never convincingly demonstrated. Inhabitants of India, a country subject to endemic variola major for some two thousand years, remained highly susceptible to the effects of the virus, case-fatality rates of over 20% among unvaccinated individuals being common right up to the time of eradication. However, it is impossible to read the accounts of smallpox among the indigenous inhabitants of the Americas (North America: Stearn & Stearn, 1945; Mexico: Crosby, 1967; Peru: Hemming, 1970; Brazil: Hemming, 1978) without suspecting that the Amerindians, an unexposed population when smallpox was first introduced into the Americas, were more susceptible than unvaccinated whites or Negroes. When variola minor was introduced into New Zealand in 1913 from the USA, there were 114 reported cases among Europeans, with no deaths, and 1778 reported cases among the local Polynesians (Maoris), with 55 deaths (Dixon, 1962). People of the Maori race had never before been exposed to smallpox.

It seems likely that a disease as lethal as smallpox must have exerted some selection for more resistant genotypes within populations in which it had been endemic for centuries. Such selection was readily demonstrated among European rabbits exposed to the poxvirus disease myxomatosis in as short a period as 10 years (Fenner & Ratcliffe, 1965), but this was initially a much more lethal disease and it was possible to test rabbits experimentally to determine their genetic resistance. As noted in Chapter 3, the only tests of genetic susceptibility that were conducted in man related to the possibility that deaths due to smallpox had some effect on the present-day distribution of genes of the ABO blood group system. The results reported were unconvincing but do not exclude the possibil-

ity that the selection of more resistant genotypes had indeed occurred in countries such as India. The linkage between cytotoxic T-cell activity, which is important in the process of recovery from orthopoxvirus infections, and the major histocompatibility antigens (HLA in man) suggests that the latter may have been important in influencing resistance to smallpox (Chapter 3). However, very few relevant studies were carried out and no definitive data were ever obtained.

#### *Age*

The age incidence of smallpox depended mainly on the acquired immunity of the exposed population, whether due to vaccination, variolation or prior natural infection. In the absence of protective immunization, the age incidence reflected the level of endemicity. Thus, when populations were first exposed to smallpox, persons of all ages and both sexes were affected. However, if smallpox was endemic, as in the larger cities of Europe in the 17th and 18th centuries and in modern India, it was mainly a disease of childhood. On the other hand it was less explicitly a children's disease than measles or even chickenpox. In the Intensified Smallpox Eradication Programme it was found that more than one-quarter of the cases occurred among the adult population, even in India (see Table 4.2) and Bangladesh (Chapter 16, Table 16.17).

Rural areas and small villages often escaped infection for several years, and when the disease was introduced it usually affected most of the large proportion of susceptible persons that had accumulated, thus causing much greater devastation in terms of economic disruption than was the case in places in which the disease was always present.

Apart from special physiological factors such as pregnancy (see below), and in the absence of immunizing infections with either variola virus or a related orthopoxvirus (e.g., vaccinia or cowpox), the severity of smallpox, as indicated by the case-fatality rate, was greatest in the very young and the elderly (see Tables 4.2-4.5). The great susceptibility of the very young is shown in all series of figures; it was more difficult to obtain clear-cut evidence of the level of resistance in elderly persons because of the opportunity that they had of being vaccinated or of becoming infected with variola virus earlier in life. What is clear from all data is that case-fatality

rates in the age group 5-14 years were much lower than in any other age group.

### *Physiological factors*

Apart from severe immunological deficiency states (see Chapter 3, Fig. 3.8), which, for most of history everywhere and in the countries in which smallpox had been endemic after 1967, would usually have led to death from infection during infancy or early childhood, pregnancy was the physiological state associated with the highest susceptibility to severe disease and death. Rao's data (Rao, 1972), summarized in Chapter 1, illustrate well the severity of smallpox in pregnant women; other investigators report similar findings (e.g., Dixon, 1948).

It is difficult to obtain data on the effects of nutritional deficiencies on the severity of smallpox, apart from the suggestion (Dixon 1962) that blindness due to smallpox occurred most frequently in ill-nourished subjects. Epidemiologists working in India during the eradication campaign formed the impression that cases of smallpox were more severe and deaths more frequent among ill-nourished villagers and refugees than in better-nourished subjects, but no reports have been published which document a relationship between malnutrition and smallpox comparable to that claimed for measles (Gordon, 1976).

### *Occupational risk*

Occupational risk was related directly to the possibility of unvaccinated or inadequately vaccinated persons coming into close contact with cases of smallpox. In Europe and the USA in the period since the Second World War, nurses in particular, and doctors to a lesser extent, were often inadequately vaccinated, although they could be exposed to massive doses of virus when treating imported cases, especially cases of unrecognized haemorrhagic smallpox. Perhaps because of the effects of large doses of virus, the case-fatality rate in nurses exposed to imported cases was sometimes very high.

### **Social Factors**

The spread of smallpox in a community depended not only on the biological factors just elaborated, the excretion of virus and the

infectiousness of cases, the mode of transmission and individual susceptibility, but also on a variety of social factors that affected the opportunities for susceptible persons to come into close contact with sources of infection, primarily overt cases of smallpox. These varied from one society to another. In many countries with well-marked dry and rainy seasons, the population was much less mobile during the rainy season, and smallpox was more confined. In the dry season, travel to markets, religious festivals, fairs and similar gatherings enhanced the opportunities for the widespread seeding of cases into previously unaffected communities. Another factor, prevalent in Indonesia, was the habit of exhibiting children infected with smallpox and taking them on visits to relatives (see Chapter 13).

In contrast to diseases such as leprosy, syphilis and gonorrhoea, no social stigma was attached to smallpox, which lessened the tendency to conceal cases. Nevertheless, in a number of communities in India and in parts of Africa, cases were hidden from the public health authorities because families distrusted the local infectious disease hospitals, or because religious beliefs generated opposition to vaccination, which would have been administered to family contacts if a case had been discovered. Such concealment caused some of the most persistent outbreaks in regions otherwise free of smallpox—e.g., the Faith Tabernacle outbreak in Nigeria (WHO/SE/68.3, Thompson & Foege), and the outbreak among the Mazezur people in Botswana (WHO/SE/74.69, Presthus & Sibiyi; see Chapter 20). During national eradication programmes, cases were sometimes concealed by both local and national health service staff, the former because they feared reprimands based on accusations of inadequate vaccination and the latter for reasons of national pride. The reward system did much to minimize concealment by local health staff.

### **Demographic Factors**

The size and density of the population at risk affected the chances of contact between susceptible and infectious persons, and thereby the extent and rapidity of the spread of smallpox. These factors have been better analysed with measles than with smallpox, but the same principles hold for both diseases, although the transmission of measles is more

Fig. 4.10. Relationship between population density and the duration of epidemics of measles. The average distance, in kilometres, between newborn infants added to the respective populations each year is given in terms of the inverse square root of the number of new susceptible individuals added to the population per square kilometre. In island populations of roughly comparable size, the duration of epidemics was inversely proportional to the density of the population. (From Black, 1966.)

efficient and rapid than was the spread of smallpox. Black (1966) has shown that in populations of about the same size, measles spread more rapidly and outbreaks terminated sooner in areas of greater population density (Fig. 4.10).

During the smallpox eradication campaigns WHO epidemiologists found that population density, when translated into the density of the susceptible population—i.e., the number of unvaccinated persons per square kilometre—was a useful concept for assessing the difficulty of controlling smallpox by mass vaccination in different endemic countries or different regions within a country (Arita et al., 1986). The effects of population density on the number and density of unvaccinated persons remaining after vaccination coverage at various levels is shown in Table 4.11. It is clear that a vaccination coverage of 80%, which was once recommended by WHO as being adequate to interrupt the transmission of smallpox, may leave a population density of 100 unvaccinated subjects per square kilometre or more in countries with a high population density, such as Bangladesh. This is very much higher than the overall country-wide population density of any African country. Arita et al. (1986) provide an example. In 1967 there was

Table 4.11 Effects of population density on the numbers of unvaccinated persons remaining per unit area ( $\text{km}^2$ ), at various levels of vaccination coverage<sup>a</sup>

Persons per $\text{km}^2$	Number of unvaccinated persons remaining when vaccination coverage is:				
	20%	40%	80%	90%	95%
500	400	300	100	50	25
300	240	180	60	30	15
100	80	60	20	10	5
25	20	15	5	3 <sup>a</sup>	2 <sup>a</sup>
10	8	6	2	1	1 <sup>a</sup>

<sup>a</sup> Rounded to nearest integer.

a vaccination coverage of 80.8% in the Matlab Thana, an area of about 194 square kilometres in Bangladesh. The population density was 582 per  $\text{km}^2$ , so that the density of unvaccinated persons was 112 per  $\text{km}^2$ . In that year 119 cases of smallpox were reported (and probably many more occurred). This is not surprising; it would be highly unlikely that smallpox could have been eradicated from Nigeria (population density 54 per  $\text{km}^2$ ) or the Philippines (population density 116 per  $\text{km}^2$ ), for example, with no vaccination at all. Clearly, mass vaccination alone was doomed to failure in countries with high population densities; control could only be achieved when it was supplemented by a vigorous campaign of surveillance and containment (see Chapter 10). Even in countries with low population densities, surveillance and containment greatly accelerated the achievement of eradication.

The age structure of the population affected the average severity (and case-fatality rate) of smallpox, since the very young, the elderly and pregnant women had particularly high case-fatality rates. Males aged between 5 and 20 years were important in extrafamilial spread, since they moved between family groups more frequently and readily than other segments of the population and often sustained relatively mild infections, so that they were important both as "exporters" and "importers" of the disease into previously unaffected family groups. The destruction of whole tribes that occurred when smallpox was first introduced into the populations of Amerindians in the Americas and Hottentots in South Africa (see Chapter 5) was due to a combination of the lethal effects of the disease itself in what were immunologically and genetically "naïve" populations, and the

social disruption and famine that accompanied the simultaneous illness of many adults of active age, as well as persons in other age groups, in these subsistence societies.

### Political and Economic Factors

The level of economic development of communities generally determines the level of health services (Fig. 4.11). The higher the level of economic development, the more effectively did surveillance and containment principles apply and the earlier was variola major, in particular, eliminated from the country (see Chapter 8).

Variola minor posed an unusual problem. Because of its low case-fatality rate compared with variola major and the lack of sequelae (facial pockmarks), it had long been tolerated as an endemic disease even in affluent countries such as the United Kingdom and the USA. In poor developing countries, such as Ethiopia, variola minor ranked very low as a national public health problem, and in the 1970s it was much more important for the rest of the world than for those countries to eliminate the disease. This justified the much larger input of international manpower and funds into the programmes in the poorer countries, in order to achieve global eradication.

### Variolation and Laboratory-Associated Smallpox

Although close contact with overt cases was responsible for the vast majority of cases of smallpox, there were two other potential sources of infection: variolation and the smallpox laboratory. For many centuries and as recently as August 1976, some cases of smallpox originated from the practice of variolation (see Chapters 6, 14 and 21). Such cases of inoculation variola themselves constituted potential sources of infection for susceptible subjects in close contact with them.

Until the 1970s, laboratories in endemic countries and in countries liable to importations conducted studies in the diagnosis of smallpox and often held stocks of variola virus to assist them in this work. Laboratory procedures are associated with some risk of infection both for those working with viruses that are pathogenic for man (accidental injection, trauma) and for visitors to such laboratories, which may use procedures that generate aerosols. Of all the dangerous human pathogens, variola virus was regarded by virologists as among the safest with which to work in the laboratory, since regular vaccination and revaccination provided complete protection to the workers involved. However, administrative mistakes sometimes occurred and a few cases of laboratory-associated infection

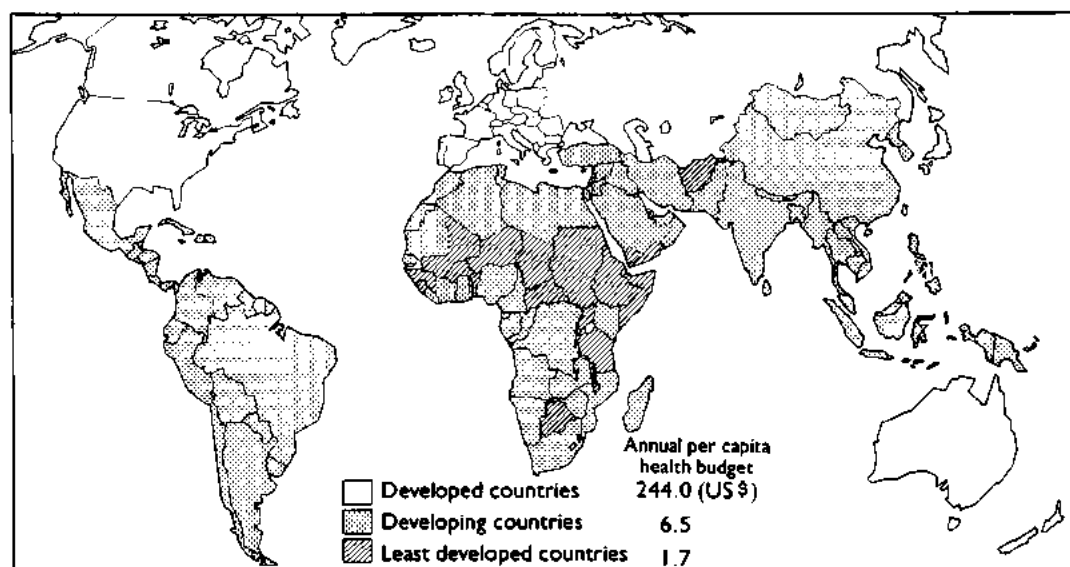

Fig. 4.11. National levels of economic development, as determined by the United Nations on the basis of average per capita income for the year 1982. Average per capita expenditures on health in US\$ are also shown.

were documented in non-endemic countries. It seems likely that cases may occasionally have occurred in endemic countries also, but the source would have been more difficult to identify with certainty. The importance of the laboratory as a potential source of infection is discussed in Chapter 30.

### PATTERNS OF SPREAD IN POPULATIONS

In the earlier sections of this chapter the infectivity of cases of smallpox and the susceptibility of individual human beings were discussed. The final section is concerned with various aspects of the spread of smallpox in populations, looking first at the situation in countries as a whole and then at small communities, including institutions. Several case studies are analysed which describe the epidemiology of smallpox in rural and urban settings.

#### Spatial Distribution

Secular trends in the occurrence of smallpox dealt with earlier in this chapter were drawn from the numbers of cases reported annually by different countries. The fact that cases were grossly and continually under-reported almost everywhere meant that these figures greatly underestimated the incidence of the disease. Further, by ascribing cases to countries they fail to express the spatial distribution of smallpox. Even when smallpox was essentially uncontrolled it was never uniformly distributed within a country. An "epidemic year", for example, usually indicated a high incidence of the disease not throughout a country, but in a number of scattered villages and towns. Although smallpox remained endemic throughout the year in the large cities of endemic countries, it occurred as many small outbreaks in different suburbs and districts within the city. As the maps showing the falling incidence of smallpox in India from 1972 onwards illustrate (Basu et al., 1979), the distribution of the disease by district was patchy, and it was patchy even within affected districts.

Effective public health measures in non-endemic countries limited the spread of smallpox after importations, usually to the family and close contacts of the index case, but sometimes, as in Yugoslavia in 1972, unrecog-

nized cases spread the disease more widely before its nature was recognized.

#### The Rate of Spread within Small Groups

The devastating effects of smallpox in non-immune populations in the Americas, southern Africa and the islands of the Pacific Ocean (see Chapter 5) gave rise to the view that it was one of the most infectious of all diseases. It is true that very brief exposures of susceptible persons to a case did occasionally lead to infection. For example, one case in the outbreak at Meschede, described above, was a person who had never been in face-to-face contact with a case of smallpox and had been exposed to possible airborne infection for a period of 15 minutes or less. The last person to contract endemic smallpox in the world—the unvaccinated hospital cook Ali Maow Maalin—was exposed to the disease for a few minutes only, while he directed a vehicle carrying two active cases of smallpox from the hospital in Merca, Somalia, to the home of the local smallpox surveillance team leader (Deria et al., 1980). Sometimes one index case infected a dozen or more people, as in the outbreak in Yugoslavia in 1972 (see Chapter 23). These episodes, however, were exceptional. Epidemiologists engaged in the global smallpox eradication campaign in Africa, South America and Asia agree with Dixon (1962) that smallpox usually spread rather slowly.

Attempts have been made to express quantitatively the infectiousness (or contagiousness) of different human diseases by calculating in various ways the proportion of cases among exposed contacts. The most widely used figure is the secondary attack rate—i.e., the proportion of susceptible individuals exposed to an index case within a household who became infected within the expected transmission interval of the disease. It is surprisingly difficult to obtain suitable series of data to make this calculation; often the term "secondary attack rate" has been used to include all subsequent attacks (first, second and third generation cases). Hope Simpson (1952) developed a measure that makes use of results of second and later generation attacks to provide a figure comparable to the first generation secondary attack rate—what he called the susceptible-exposure attack rate.

Some figures for measles, chickenpox and smallpox are set out in Table 4.12. The numbers available for the calculation of the

secondary attack rate were often quite small and the reported secondary attack rates varied widely. For variola major, the overall average secondary attack rate was 58.4% in unvaccinated family contacts, and 3.8% in vaccinated contacts. Vaccination protected most close family contacts from overt disease (but not necessarily from subclinical infection—see Heiner et al., 1971a). The highest secondary attack rates were those reported for Pakistan by Heiner et al. (1971a) and Mack et al. (1972a). These workers suggested that one of the causes of this phenomenon might have been the dry meteorological conditions prevailing for most of the year in the Punjab, compared with other parts of the Indian subcontinent. On the basis of secondary attack rates in susceptible subjects, smallpox appears to have been somewhat less infectious than either measles or chickenpox, since the figures for chickenpox exclude subclinical infections, which occur in at least 5% of varicella virus infections but are extremely rare in unvaccinated persons infected with variola virus.

This comparison of the secondary attack rates of smallpox and other common infec-

tious diseases fails to take cognizance of an important feature of variola major, which substantially decreased the rate at which it spread outside the household. Patients in the prodromal stage of variola major, before the rash had appeared and before they could transmit infection, were usually quite ill, with toxæmia, headache and backache. Most took to bed, so segregating themselves from the general community, although not from their household contacts. In contrast, patients in the early and highly infectious stages of chickenpox and measles have few symptoms and are usually mobile, and thus spread these diseases to school and street contacts as well as to members of the household. Although its inherent transmissibility was probably lower than that of variola major, because less virus was excreted in the oropharyngeal secretions, variola minor resembled chickenpox in the mobility of infectious patients, which partly accounts for its persistence in many countries after variola major had been eliminated.

Another measure of infectiousness is the duration of outbreaks in particular community units. There are many records in the

literature of the slow spread of smallpox—for example, the outbreak of variola minor in New South Wales (Australia) in 1913–1917 (Cumpston & MacCallum, 1925; see Chapter 8) and among nomads (see below). Smallpox sometimes took several generations of infection to spread through quite small populations.

### Spread in Institutions

Because of the importance of face-to-face contact in the transmission of smallpox, the household or family unit was by far the most frequently affected group. Nevertheless, some institutions, especially hospitals and schools, and public events, such as fairs and religious festivals, played an important part in the dissemination of smallpox.

#### Hospitals

The role of hospitals was particularly significant in amplifying outbreaks of imported smallpox, for undiagnosed and misdiagnosed cases were often admitted into general wards, and the proportion of unvaccinated or poorly vaccinated hospital personnel and patients was usually high (Millar, 1965). Over half the cases that occurred after importations of variola major into Europe between 1950 and 1971, and all the large outbreaks, were to be found among persons associated with hospitals, either occupationally or as patients or visitors (Mack, 1972). An outbreak in Glasgow in 1950 (Laidlaw & Horne, 1950) was characteristic. An Asian seaman with 4 vaccination scars and a history of revaccination 3 years earlier was admitted to hospital with what was regarded by an experienced consultant as chickenpox, but was in fact modified-type smallpox. Thirteen of the 18 cases which ensued were infected in hospital, including 10 members of the hospital staff. Six died, all of whom were unvaccinated or had failed to respond to vaccination after exposure.

The experience in the epidemic in Yugoslavia in 1972 (Stojkovic et al., 1974) was particularly dramatic: an undiagnosed case of haemorrhagic-type smallpox infected 2 contacts in a bus and then a total of 36 persons in 3 hospitals to which he was admitted.

Hospitals sometimes played a role as amplifiers in countries with endemic smallpox. Almost everywhere, they were important

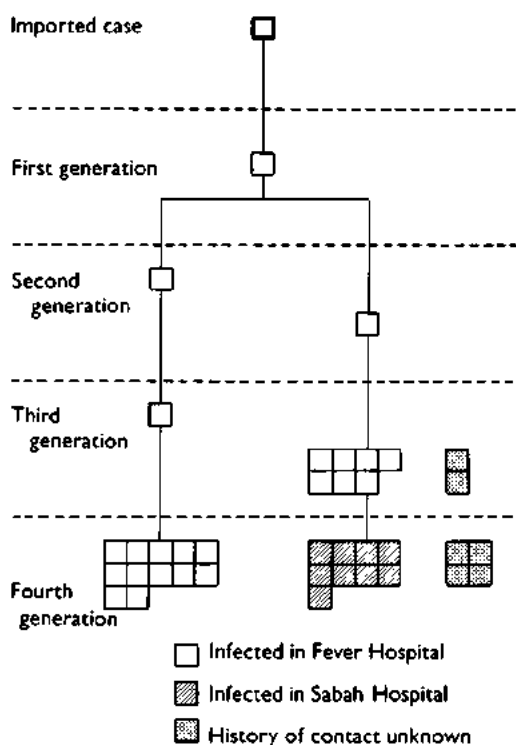

Fig. 4.12. The pattern of transmission of smallpox in an outbreak in Kuwait in which two hospitals were the principal foci of infection. (From Arita et al., 1970.)

disseminators of smallpox. Obviously, if all staff were regularly vaccinated and patients and visitors vaccinated on entry—as ideally they should have been—the risk of spread would have been very low. However, with a few exceptions, such as the Infectious Diseases Hospital in Madras (Rao, 1972), this did not occur. Two outbreaks exemplify the risk.

Kuwait is a small country which in 1967 had been free of endemic smallpox for the previous 10 years, but which was constantly exposed to the risk of importations from nearby endemic countries. Smallpox misdiagnosed as chickenpox spread in the Fever Hospital over a period of 2 months before a second generation fatal case was correctly diagnosed, after it had caused 9 third generation cases. One of these, unrecognized, was transferred to another hospital (Sabah), where it produced several more cases (Fig. 4.12). Twenty-one of the 39 cases were in children under 4 years of age; only 8 patients, 6 of them aged 15 years or more, had ever been vaccinated. In contrast to the usual situation in Europe, all cases, except one vaccine-modified attack, occurred among patients rather

than nurses or other hospital personnel, whose immune status had been maintained by regular revaccination (Arita et al., 1970).

An outbreak in a children's hospital in Brazil described by Morris et al. (1970a) demonstrates clearly the importance of the hospital as a potential focus for transmission in countries in which variola minor was endemic. The epidemic had been smouldering in the community and the hospital for at least 10 months before it was extinguished and 40 of the 51 cases that occurred in the hospital during 1967 were certainly or possibly (4 cases) hospital-associated. Over the period, there were at least 11 and possibly 15 separate introductions of smallpox into the hospital, which formed a continuous source of infection because visiting was not restricted and smallpox cases were treated in the outpatient clinic. Only one hospital employee was infected—a kitchen worker who had never been successfully vaccinated.

### *Schools*

Because of their accessibility, schoolchildren in endemic countries were usually well vaccinated. Unvaccinated children in the infectious stages of variola major were usually too ill to attend school. Even with variola minor, contacts between children in the household or, to a lesser extent, in playgrounds appeared to have been more important than their contacts at school (Angulo et al., 1968). Space-time cluster analysis of variola minor within two schools suggested that transmission was most likely to occur from infected children to susceptible children sitting next to them (Klauber & Angulo, 1974a); studies in schools when two or three shifts of pupils occupied the same classroom each day revealed that contaminated desks or other fomites played no part in spread (Klauber & Angulo, 1974b).

In a study in Mali, Imperato (1970) found that smallpox spread much more rapidly and extensively among schoolchildren than among equally inadequately vaccinated children of the same age who did not attend school. The epidemic was confined to a group of straw buildings in which there was severe overcrowding and did not spread to children in less crowded cement-block buildings in the same school compound. However, even in the straw buildings transmission, mostly between susceptible and infected persons in close

contact, was slow and went on for a long time because of the absence of an effective response by the local health personnel.

### *Markets, fairs and religious festivals*

Markets are regular institutions at which households mingle; fairs and religious festivals, although held less frequently, draw attendance from much wider areas. Both are important as mechanisms for the wide dissemination of infectious diseases, because of the dispersion of participants during the incubation period. Great international religious festivals, such as the pilgrimage to Mecca, are kept under strict medical surveillance and appeared to have played only a minor role in the international spread of smallpox during the latter part of the 20th century, although it seems likely that some outbreaks did occur but were concealed. The national religious festivals in India were always important for the dissemination of smallpox, and in the later stages of the eradication campaign they served as convenient observation posts for sampling the vaccination status and awareness of smallpox in village populations (see Chapter 15).

On rare occasions funeral ceremonies provided an opportunity for the spread of smallpox. When death due to unrecognized smallpox occurred, relatives, friends and other associates who were obliged to attend the funeral could be exposed to a variety of sources of virus (Hopkins et al., 1971c). Like markets or fairs, funerals were important because the participants subsequently dispersed and could then produce secondary cases among widely separated family groups.

### **Dispersal by Travellers**

Because of the long incubation period of smallpox, travellers of various kinds—migrant workers, nomads, tramps, bus and train passengers, and air travellers—could cover long distances while apparently healthy and introduce the disease into areas far removed from the place in which they had acquired the infection. The situation was dramatically illustrated by importations into European countries by air travellers (Hagelsten & Jensen, 1973; see Chapter 23), but the movement of train and bus travellers in endemic countries was no less important. Fellow-travellers

were sometimes infected when ambulant patients, perhaps with vaccine-modified smallpox, travelled in buses or trains (see, for example, WHO/SE/72.41, Suleimanov & Mandokhel). Usually the travellers became infectious after arriving at their destination, where they initiated new outbreaks. Perhaps the most dramatic of such instances of dispersal of smallpox to distant areas were those from the Jamshedpur industrial complex in Bihar, India, in 1974 (see Chapter 15, Fig. 15.20). During a 6-week period, between the end of February and mid-April 1974, travellers from Jamshedpur caused nearly 300 outbreaks in other Indian states, dispersal occurring mainly through train passengers travelling from the Tatanagar railway station. During 1974 there were many exportations from India to Nepal and in 1975 smallpox was reintroduced into India from Bangladesh on 32 occasions (see Chapter 15).

Because of their greater mobility, adult men were much more likely than women or children to acquire smallpox outside the home; the movement of sick peasants or workers from the city back to their villages appeared to be important in the maintenance of smallpox in some rural areas in the Indian subcontinent (Thomas et al., 1971a; Thomas et al., 1972; Sommer & Foster, 1974). Indeed, it was suggested that in Pakistan the cities were the reservoir of smallpox during the monsoons, the disease being carried back to the rural areas after the rains. However, when effective active surveillance was introduced, a number of affected localities were found in rural areas immediately after the monsoons, in spite of reports of "no transmission" during the rains (see Chapter 14). Not surprisingly, in countries such as India, in which 80% of the population was rural, the predominant travel pattern (74%) was from one rural area to another, and smallpox transmission followed the pattern of population movement.

#### *Dispersal by refugees*

Although they constituted a special type of traveller, refugees were of particular importance in the spread of smallpox, because of the vast numbers involved in the flight from war- and famine-stricken areas. Such dispersal was directly responsible for the re-establishment of endemic variola major in Bangladesh in 1972 (see Chapter 16). Many other instances occurred, both between and especially within countries. Movement of refugees provided

almost ideal conditions for the promotion of spread—large numbers of persons of all ages living in close proximity under very unsatisfactory conditions, often suffering from malnutrition and often poorly vaccinated. The isolation of cases was difficult or impossible.

#### **Illustrative Case Studies in Rural Areas**

In the developing countries in which smallpox was most recently endemic the vast bulk of the population lives in villages in the rural areas. In India, for example, the 1971 census figures showed that 80% of the population of 548 million lived in 580 000 villages, of which 318 000 had a population of less than 500. There were only 148 towns and cities with a population of more than 100 000. In Bangladesh and in most countries of Africa the proportion of population in the rural areas was even higher. In some countries, such as Afghanistan and Somalia, some of the rural population lived a nomadic life; these nomads presented special problems in smallpox eradication programmes.

#### *Studies in Africa*

Henderson & Yekpe (1969) described the spread of smallpox in a village in southern Benin, in which about half the population of 300, as well as about half the members of the infected households, had old vaccination scars. The chronology of the epidemic and the probable chains of transmission which started with the movement of an infected woman and her children back to the village are shown in Fig. 4.13. The 3 cases infected outside the village lived in house A and the disease spread to 5 contiguous houses (B–F) by moving from one infected household to the uninfected household nearest to it. Seventeen of the 28 persons living in that cluster of houses (A–F) became ill. A 17-year-old boy living in house G, who carried food to persons in the infected cluster of households, became ill but produced no secondary cases; both his parents had vaccination scars. Infection was brought to house H by the "*grand féticheur*" (Case No. 22), whose occupation involved frequent contacts with all cases of smallpox, and he was probably responsible for the other 6 cases in the village, in houses H and I. The 2 patients in household I joined the *grand féticheur* in the funeral ceremonies of smallpox victims. Frequent casual contact occurred between the

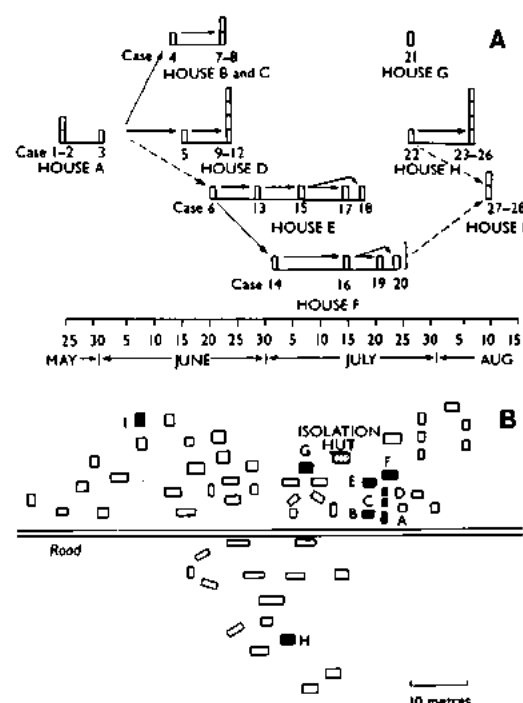

Fig. 4.13. The spread of smallpox in a village in Benin of 300 inhabitants, living in 59 houses, extending from May to the end of August 1967. A: Chronology and spread. Solid lines = routes of transmission; broken lines = probable routes of transmission. B: Location of households. (Based on Henderson & Yekpe, 1969.)

villagers in general and the smallpox sufferers, although once the rash had developed the patients were generally avoided.

The striking feature of this epidemic was the spatial localization of the disease, which reflected intimate social contact between at least some members of the affected households. Once smallpox had been introduced into a household, secondary cases occurred within it. The transmission of smallpox appeared to stop when the number of susceptible individuals in the village who were in casual contact with cases was still large but the supply of such persons in prolonged and intimate contact with cases was virtually exhausted. Even among the household contacts smallpox was not highly contagious; prolonged or intimate exposure was usually necessary. Because of this pattern of spread, it is not surprising that smallpox was eliminated from many African countries much more rapidly than had originally been anticipated (see Chapter 17).

### *Studies in Brazil*

Similar observations emerged from a study of the spread of variola minor in a semi-rural school district in São Paulo, Brazil, in which there were two types of social agglomerates: school classes (Angulo et al., 1964) and households (Angulo et al., 1967). All the secondary cases in the 12 infected households resulted from a single introduction by a known primary case of smallpox, who was usually a child infected in the school. Infection occurred only among persons in intimate and face-to-face contact, either in the household, in the school, or in shared household facilities (Angulo et al., 1968).

### *Studies in the Indian subcontinent*

Thomas and his colleagues have reported detailed studies of smallpox in rural areas of Pakistan and Bangladesh (see Chapters 14 and 16). Their investigations in Bangladesh (Thomas et al., 1971a, b) showed that smallpox did not remain indefinitely endemic in a rural district in which 113 000 inhabitants resided in 132 villages scattered over an area of about 200 square kilometres. During a period of 12 months, 119 cases of smallpox occurred in 30 outbreaks in 27 widely dispersed villages. Inter-village spread occurred in only one case; in the other 21 outbreaks whose source could be determined, smallpox was introduced by a landless peasant from the village in question who had contracted smallpox during a visit to a city to obtain employment. The probability of an introduction was correlated with the population size of the village, and thus with the probable numbers of landless peasants from each village seeking employment in the cities. With the introduction of smallpox into a village, secondary cases appear to have occurred more frequently outside than inside families. Nevertheless, the secondary attack rates among unvaccinated persons were highest within families.

A further, substantially larger study was carried out in Pakistan (Mack et al., 1972a, b; Thomas et al., 1972). The most striking differences between the two studies were the very high secondary attack rate (88%) among unvaccinated contacts within compounds and the high proportion of cases (78%) resulting from spread between rather than within compounds. The explanation for

the very high secondary attack rate in Pakistan is not clear; possibly it was due to the low humidity prevailing in the Punjab for most of the year. As in Bangladesh, smallpox was not maintained as an endemic disease within the rural areas, even in one as large as 6000 square kilometres with 1.2 million inhabitants. Over half the outbreaks occurring in the study area were ultimately traced to cities, emphasizing the significance in Pakistan of these large aggregations of population for the maintenance of the disease.

Investigation in Pakistan by Heiner et al. (1971b) confirmed the high secondary attack rate in the Punjab, which reached 77% in unvaccinated compound contacts and 4.8% in previously vaccinated contacts, all of the latter having been exposed to severe or fatal index cases. Further, vaccinated persons generated many fewer cases among their contacts (4%) than did unvaccinated index cases (11.5%) (see Table 4.10), reflecting the greater severity of the disease in unvaccinated subjects.

Another investigation in rural villages in Pakistan, which was mainly concerned with inapparent infections (Heiner et al., 1971a), has been discussed at length in Chapter 1. Here we would note that in this study, village residents who were not household or compound contacts of cases were taken as one of the control groups. In contrast to vaccinated compound contacts, over half of whom had had overt or inapparent smallpox, only 6.5% of these other vaccinated villagers in this control group had sustained inapparent infections (none had overt smallpox), again showing the importance of intimate face-to-face contact in the transmission of smallpox.

#### *Prolonged transmission among nomads*

Nomads constituted a special problem in the Horn of Africa, sub-Saharan western Africa and Afghanistan. On general principles, it could be predicted that smallpox would rarely persist for long in such small isolated populations, even in the absence of control measures. This was indeed usually the case. Outbreaks among nomads constituted 68% of 843 outbreaks in Somalia in 1977, but in only 10 of them did prolonged transmission occur (Table 4.13). The best documented of these outbreaks, in Mandeelo village (Foster et al., 1978), is described in Chapter 22. As indicated in Table 4.13, transmission was interrupted very soon after outbreaks in nomads were detected, and in some instances the last case had occurred before the outbreak was detected. Similar prolonged persistence of smallpox in nomadic groups of less than 15 persons have been described in both Cameroon and Niger (Henderson & Yekpe, 1969).

This slow and prolonged transmission was due to the balance between the supply of susceptible persons and the transmission rate. Nomads were usually poorly vaccinated and patients with variola minor were often ambulant throughout their illness. The transmission rate was low because most of the activities of nomads occurred in the open, where opportunities for face-to-face transmission by large-particle aerosols were greatly reduced. As noted above, these circumstances usually led to the spontaneous termination of outbreaks (in 98.2% of outbreaks), but if transmission was maintained it continued for many weeks, even in these very small populations.

Table 4.13 Prolonged transmission of smallpox in several nomadic encampments in Somalia in 1977<sup>a</sup>

Locality	Population	Number of cases	Number of days from first to last case	Date of:		
				First case	Last case	Detection
Darta	55	14	163	17 Feb.	1 Aug.	20 Aug.
Oridan	35	24	152	21 Jan.	23 June	28 June
Loala	98	20	106	22 March	6 July	22 June
Bilahey	75	23	95	14 March	8 June	19 June
Madhare	35	9	80	6 March	24 May	18 May
Berdebiote	65	9	74	20 April	4 July	5 July
Boldwene	50	6	73	26 March	8 June	17 May
Abdijelib	11	6	70	25 Feb.	7 May	24 April
Mandeelo	46	21	68	23 April	1 July	23 June
Shafa	60	12	65	28 June	1 Sept.	12 Aug.

<sup>a</sup> The great majority of outbreaks in such groups were rapidly detected and controlled, or the chain of transmission was interrupted spontaneously. (Based on Jezek et al., 1981.)

### Illustrative Case Studies in Urban Areas

Outbreaks of smallpox in non-endemic countries since 1950, most of which occurred in urban settings, are discussed in Chapter 23. Of more significance than these episodes, in relation to the global smallpox eradication programme, was the pattern of spread in urban areas in countries in which smallpox was still endemic. Only a few reports of such situations have been published, mainly referring to cities in the Indian subcontinent (Madras: Pandit et al., 1959; Rao et al., 1968a; Rao, 1972; Calcutta: Mukherjee et al., 1974; Lahore and surroundings: Ali & Heiner, 1971; Thomas et al., 1972; Bangladesh: Sommer & Foster, 1974; Brazil (variola minor): Rodrigues-da-Silva et al., 1963; Azeredo Costa & Morris, 1975).

Transmission to household contacts in some cities, e.g., Madras (Rao, 1972), showed much the same pattern as that in rural areas; transmission was usually more common among intrafamilial than extrafamilial contacts, even when all those studied lived in compounds in which families shared an entrance, toilet facilities and a bath. The importance of the local social arrangements is shown by the fact that in Calcutta Mukherjee et al. (1974) found that the attack rates among household and compound contacts were very similar; in this situation the mixing of the inhabitants was so intimate that each compound could be regarded as a single large family.

In many endemic countries the larger towns and cities constituted the major reservoir of smallpox during the wet season. Sarkar et al. (1970) studied the epidemiology of off-season cases in Calcutta in 1967 and 1968. Most of the few cases that occurred during the months June–November of each year were in beggars and footpath dwellers or in manual labourers who did not work in fixed places and lived in the bustees (slum areas). Successive cases were sometimes widely dispersed, but the majority of cases could be grouped into 6 outbreaks in the bustees, different groups being involved in 1967 and 1968. Several cases were probably associated with introductions from villages outside Calcutta, and in one instance there was evidence that infection was introduced from Calcutta into a village 30 kilometres away in May 1968, maintained there by serial transmission, and reintroduced into another part of Calcutta in September 1968.

Several reports refer to the maintenance of smallpox in small pockets of unvaccinated individuals in otherwise well-vaccinated populations. In Lahore, for example, Ali & Heiner (1971) found that in a situation in which 93% of the population had vaccination scars or a history of smallpox, the disease could persist for most of the year, mainly because of the high concentration of unvaccinated children under 3 years of age and of older persons in whom the immunity conferred by primary vaccination many years before had waned.

Experience in Indonesia (see Chapter 13) provided one of the earliest and clearest demonstrations of the ineffectiveness of mass vaccination alone as a means of eliminating smallpox from populous countries. It used to be held that a vaccination level of 80% would suffice to raise the herd immunity to such an extent that transmission would cease (see Chapter 9). However, in Indonesia in 1969 and 1970 chains of transmission of variola major were maintained in communities in which the overall vaccination rate was about 90%. This happened because of the high population density (see Table 4.11), and because a large proportion of the unvaccinated were in the age group 0–4 years. The Indonesian practice, mentioned earlier in this chapter, of taking children with smallpox on social visits to their neighbours and relatives maintained a chain of transmission in this section of the population.

Thompson & Foege (WHO/SE/68.3) demonstrated that the existence of special groups who, for social or religious reasons, refused vaccination was of significance in maintaining endemic smallpox within an otherwise well-vaccinated urban community in Nigeria. The concealment of cases played an important role in the development of the epidemic, but the disease spread quite slowly (32 recognized cases over a period of 11 weeks), even in a compound where nobody had been vaccinated. In spite of frequent social mixing on religious occasions, transmission occurred most frequently as a result of family and compound contacts. Such situations were not restricted to urban areas, for the last outbreak of smallpox in southern Africa occurred among a religious sect in Botswana, who lived in closed communities in 9 small towns and likewise refused to be vaccinated (Presthus, 1974; WHO/SE/74.69, Presthus & Sibiya).

**Plate 4.4.** **A:** Thomas M. Mack (b. 1936), **B:** David B. Thomas (b. 1937) and **C:** Gordon G. Heiner (b. 1924), with Pakistani colleagues, conducted some of the most important and certainly the most comprehensive studies of the epidemiology of smallpox to be undertaken during the Intensified Programme. Working in what was then East and West Pakistan between 1965 and 1968, they demonstrated how surveillance and containment measures could be highly effective even in some of the most heavily infected areas.

### SUMMARY

The basic facts of the epidemiology of smallpox may be summarized as follows:

(1) Smallpox was a specifically human disease; there was and is no known animal reservoir of variola virus (see Chapter 30).

(2) Compared with the infectious agents of many other human viral diseases, variola

virions are relatively resistant to inactivation by physical and chemical agents; nevertheless, infection almost always involved the face-to-face contact of a susceptible subject with a person suffering from clinical smallpox.

(3) The detection and recognition of cases were relatively simple, since the rash was usually quite distinctive and occurred mainly on uncovered parts of the body.

(4) Subclinical infections with variola virus seldom occurred, except in vaccinated close contacts of cases. These individuals rarely, if ever, transmitted smallpox to others and were of little or no importance epidemiologically; almost all new cases could be traced to contacts with overt cases.

(5) An attack of smallpox was followed by death or recovery; persistent, latent or recurrent infection did not occur and cases were never infectious after the rash had gone.

(6) Different strains of variola virus differed in their virulence. Strains from outbreaks with case-fatality rates of about 1% in unvaccinated persons are designated variola minor virus. Most strains, for most of history, were associated with much higher case-fatality rates (5%–15%, and more commonly

about 25%); these strains are designated variola major virus.

(7) All strains of variola virus are indistinguishable antigenically. In the vast majority of cases, immunity to reinfection was absolute. Similar protection could be reproduced, for a period of several years, by immunization with a live virus vaccine prepared from a related orthopoxvirus, such as cowpox or vaccinia virus.

(8) There was a pronounced seasonal incidence: smallpox was essentially a winter-spring disease.

(9) Smallpox spread rather slowly. There was an interval of 2–3 weeks between each generation of cases, and even during the transmission season an index case rarely infected as many as 5 other persons.

### INTRODUCTION

Smallpox was a disease with such obvious and characteristic clinical signs and caused such dramatic and disastrous epidemics that it

was long the subject of myths and superstitions, and physicians and historians wrote much about it. This chapter provides a brief historical background, from the earliest civilizations until the beginning of the

20th century, of the occurrence of smallpox and its spread around the world. In compiling it we have drawn heavily on a recent book by Dr D.R. Hopkins: *Princes and Peasants. Smallpox in History* (Hopkins, 1983a), to which we refer readers interested in learning more about the way in which smallpox has influenced history, as well as about the history of smallpox and its control.

Smallpox was a specifically human infectious disease. One attack conferred lifelong immunity on survivors and neither chronic nor recurrent infectivity occurred among those who recovered from the acute illness. The persistence of such a disease in an endemic state within a human community was possible only if the population admitted a large regular accession of susceptible persons, either by birth or by immigration. Where appropriate and possible, estimates have been provided of the populations of some countries and continents at various times in the past, using the *Atlas of World Population History* (McEvedy & Jones, 1978) as a source-book. It must be emphasized that most of these population estimates are informed guesses rather than estimates based on reliable demographic data.

In order to provide an overview of the history of the world-wide spread and the subsequent control of smallpox, a list of important historical events that relate to this chapter and to Chapter 6 is provided in Table 5.1.

### SMALLPOX BEFORE AD 1000

Most of the early civilizations left written records, some of which describe diseases of the time. Medical historians have been able tentatively to identify some of these diseases, but the older the records the less reliable are the diagnoses. Unmistakable descriptions of smallpox did not appear until the 4th century AD in China, the 7th century in India and the Mediterranean, and the 10th century in south-western Asia. Each of these descriptions refers to what was at the time a well-known disease. Mummified human remains provide another kind of evidence of disease, which is potentially more reliable than the interpretation of ancient writings, but suitable material is very scarce. It is therefore necessary to use epidemiological intuition to make guesses about the earliest occurrence of smallpox as a human disease.

### Egypt

One of the earliest concentrations of civilized man was in the valley of the Nile and in the Fertile Crescent, which stretched from Palestine to the flood plains of the Tigris and the Euphrates. Trade and conquest made this region a single ecological unit, as far as the transmission of many human diseases was concerned. However, apart from reference to a "plague" that the Hittites were said to have caught from the Egyptians in the 14th century BC, which could conceivably have been smallpox, the written records of these civilizations, which include the Talmud and the Bible, do not refer to any disease that can be interpreted as being smallpox.

The largest and densest population in the region was in the valley of the Nile, where there may have been 1 million persons in the 3rd millennium BC and perhaps 3 million by the 1st millennium BC. As biblical and other written sources attest, Egypt was periodically visited by devastating epidemics, but none has been described which was suggestive of smallpox. However, the Egyptian practice of mummification preserved the skin, musculature and bones of a large number of royal personages, and diagnoses of the causes of death of several mummified persons have been made by palaeopathologists (Ruffer, 1921). The scientific literature mentions 3 mummies whose skin was covered with lesions that looked like those of a smallpox rash.

Ruffer & Ferguson (1911) described a smallpox-like eruption on the mummy of a middle-aged man who had died during the Twentieth Dynasty (1200–1100 BC). Section of a portion of skin showed dome-shaped vesicles in the epidermis, similar to those found in smallpox. Considering how resistant poxvirions are and how well preserved material from Egyptian mummies can sometimes be (Lewin, 1967), it is unfortunate that electron microscopy was not available at the time of this discovery, and that tissue from "smallpox" mummies has not thenceforth been at the disposal of investigators for electron microscopic examination. Ruffer (1921) mentioned that there was a similar eruption on a mummy of the Eighteenth Dynasty (1580–1350 BC) and on the mummy of Ramses V, who died as a young man in 1157 BC (Plate 5.1). Hopkins (1983a) describes some features of the burial of Ramses V that are consistent with a diagnosis of smallpox, and in 1979 he was able to examine the mummy himself:

**Plate 5.1.** The mummified head of Ramses V of Egypt (died 1157 BC) showing the pustular eruption that may have been due to smallpox. (From Smith, 1912.)

"It is one of the best preserved royal mummies in the [Cairo] museum. Inspection of the mummy revealed a rash of elevated 'pustules', each about two to four millimeters in diameter, that was most distinct on the lower face, neck, and shoulders, but was also visible on the arms. Over the shoulders especially, these pustules were pale yellow against a dark brown-reddish background, the latter partly due to cosmetic compounds used in royal mummifications during that period. On his upper face, only smaller raised pimples (one to two millimeters) could be seen, which might have been shrunken more by tighter wrappings over the forehead. It was not possible to examine the palms or soles where the presence of pustules would be highly characteristic of smallpox, because his arms were folded across his chest with the palms down, and the shroud was stuck to his soles. No such rash could be seen on the chest or upper abdomen. Earlier photographs of this mummy, published by G. Elliot Smith (1912) show that the rash is also prominent on the lower abdomen and scrotum ... Three folds in the skin over the left cheek suggest that his face may have been swollen when he died. The appearance of the larger pustules and the apparent distribution of the rash are similar to smallpox rashes I have seen in more recent victims."

One might have expected that an epidemic disease as distinctive as smallpox, which killed

pharaohs and nobles as well as the common people, would have been described in the extensive writings on medical subjects left by the Egyptians, or by their northern neighbours in Asia Minor. However, no such description exists, although in the Ebers Papyrus there is a passing reference to an illness affecting the skin which Regöly-Mérei (1966) suggests may have been smallpox.

There remains the tantalizing speculation, based on these 3 mummies, that smallpox may have occurred among the inhabitants of Egypt more than 3000 years ago, which is well over a thousand years earlier than any reliable references to the disease elsewhere in the ancient world. From here it could well have been carried to India during the 1st millennium BC, either overland by caravan or, more likely, by sea.

### India

Although there may have been a population of some 5 million in the Indus valley during the 2nd millennium BC, this civilization collapsed and disappeared about 1600 BC. A thousand years later another civilization, based on rice-growing, developed further east, and by 500 BC the Indian subcontinent had a population of about 25 million, of whom some 15 million lived in the Ganges basin, which has remained the demographic centre of the subcontinent ever since.

Holwell (1767), a physician of the British East India Company who survived imprisonment in the Black Hole of Calcutta, suggested that smallpox had existed in India from "time immemorial", and stated that it was mentioned in the most ancient Sanskrit writings, the *Atharva Veda*. Holwell's suggestions have been quoted by Hirsch (1883) and Hopkins (1983a), among others, as evidence of the occurrence of smallpox in India from very early times. Nicholas (1981), a scholar of Indian history and anthropology, contests this view.

He noted that *masūrikā*, the word used for smallpox, is found in many medical compilations produced in India since the beginning of the Christian era, but not in the more ancient *Atharva Veda*. It first appears in the compilations of Caraka and Suśruta, which were begun before the Christian era and put into their final forms in the 4th century AD. But according to Nicholas these texts say very little about *masūrikā* and refer

Table 5.1. Important events in the history of smallpox, from ancient times to 1900

Period	Africa	Americas
2nd millennium BC	? smallpox in 3 Egyptian mummies.	
1st millennium BC		
1st century AD		
2nd century		
4th century		
5th century		
6th century		
7th century	Ahrun of Alexandria describes smallpox (622).	
8th century		
10th century	Smallpox probably spread to western Africa by Arabs.	
13th century	Variolation by cutaneous route introduced into Egypt by Mamelukes.	
14th century		
15th century		
16th century	Smallpox epidemic in eastern Africa (1589). Smallpox introduced into coastal ports of western Africa.	Smallpox introduced into Caribbean (Hispaniola) (1507). Smallpox spreads from Hispaniola to Mexico (1520). Smallpox spreads to Peru (1524). Smallpox in Brazil (1555).
17th century		Severe smallpox outbreak in Massachusetts, USA (1617). Severe outbreak in Brazil (1665-1666).
18th century	Smallpox introduced into Cape Town and destroys Hottentots (1713 and 1755). Smallpox spreads in central Africa with slave traders.	Variolation introduced into North America (1721). Smallpox disrupts Colonial army at Quebec (1776). Washington orders variolation of Continental army (1777).
19th century	Further spread of smallpox in eastern and central Africa with caravans (1840s). Variola minor ("amaas") described in South Africa (1890s; 1904).	Pandemics among North American Indians (1801-1802 and 1836-1840). President Jefferson initiates vaccination of American Indians (1801). President Lincoln has smallpox (1863). Variola minor occurs in Florida and spreads throughout USA (1896-1900s).

Table 5.1. (continued)

Asia and Oceania	Europe
Epidemic spreads from Egypt to Hittites (~1350 bc) ?? smallpox.	
Compilation of <i>Suśruta Samhita</i> in India (~100 bc). Mentions <i>masūrīkā</i> , which may be smallpox.	Plague of Athens, from Egypt and Libya, spreads to Persia (430 bc). Epidemic in Sicily, from Libya (395 bc) ?? smallpox.
Smallpox introduced into China from south-west (48-49).	
	Antonine Plague spread to Rome from Mesopotamia (165) ?? smallpox.
Ko Hung in China differentiates smallpox from measles (340).	
	Bishop Nicaise of Rheims recovers from smallpox (450); becomes patron saint of smallpox.
"Elephant War" in Mecca (568) ? smallpox decimates Ethiopian soldiers.	Gregory of Tours describes ? smallpox in France and Italy (580). Bishop Marius uses term "variola".
Smallpox spreads from China to Korea (583) and from Korea to Japan (585).	
Arabs carry smallpox with invading armies to North Africa and Spain.	
Al-Razi publishes descriptions of smallpox and measles (910). First use of modern Chinese character for smallpox. First use of variolation by intranasal route in China as secret rite. <i>Ishinho</i> published in Japan (982); describes "red treatment" and isolation hospitals.	Daughter of King Alfred of England has ? smallpox.
	Gilbertus Anglicus describes clinical types of smallpox in England (1240); recommends "red treatment". First introduction of smallpox to Iceland from Denmark (1241).
King of Burma dies of smallpox. Epidemic of smallpox in Siam.	
	Severe smallpox epidemic in Paris (1438).
King of Siam dies of smallpox (1534).	Records of deaths from smallpox maintained in Geneva (1580).
Severe epidemics in Siberia (1630). Variolation by nasal route popularized in China.	Severe smallpox in most of Europe. London Bills of Mortality record 10% of deaths due to smallpox (1629). First account of smallpox in Russia (1623). Sydenham describes clinical types of smallpox, and distinguishes measles from smallpox.
Chinese emperor sends variolation teams to control smallpox in Tartary (Siberia) (1724). Variolation introduced into Japan (1744). Smallpox epidemics among aborigines in Australia (1789 and 1829).	Variolation introduced into Great Britain and Bohemia (1721). London Small-Pox and Inoculation Hospital founded (1746). Heberden distinguishes smallpox from chickenpox (1760). Dimsdale variolates Catherine the Great of Russia (1768). Smallpox cripples Spanish-French fleet attacking England (1779). Jenner describes vaccination (1798).
Vaccination introduced into India (1802), Philippines (1803), Java (1805), China (1805). Vaccination introduced into Siam (1840). Vaccination introduced into Japan (1849).	Vaccination spreads throughout Europe (1800-1801). Compulsory vaccination in Bavaria (1807). Revaccination proposed in Württemberg (1829). National Vaccine Establishment founded in England (1808). Negri in Naples begins systematic production of vaccine in cow (1845). Production in cows introduced in France (1864). Last great epidemic in Europe, after Franco-Prussian War (1870-1871). Copeman demonstrates bactericidal effect of glycerol (1892).

to it as a trivial skin disease. The first extant description of *masūrikā* as a severe and sometimes fatal disease appears in the works of Vagbhata, a physician writing early in the 7th century AD. A century later the *Nidana* of Madhava-kara included an extensive and knowledgeable chapter on *masūrikā*, treating smallpox, chickenpox and measles together. Wise (1867) suggested that the failure of earlier Indian writings to identify *masūrikā* as a severe disease indicates that smallpox may have changed its characteristics not long before al-Razi, towards the end of the 1st millennium AD, in Baghdad, described the disease as we now know it (see below). However, Chinese descriptions identify smallpox as a serious disease that was imported from the west, apparently as early as the 1st century AD.

The only suggestion of the possibly earlier existence of smallpox in the Indian subcontinent was the epidemic that attacked Alexander's army in 327 BC, when it was camped on the lower Indus, but although "scabs" are mentioned the description is so incomplete that it is difficult to be at all certain of the diagnosis.

We can speculate that smallpox was brought to India by Egyptian traders during the 1st millennium BC, to become endemic in the large population of the Ganges valley. However, there is no reliable evidence of its existence there before the description in the *Sūsruta Samhita*, which appears to relate to a rather trivial skin disease rather than a generalized infection with a high mortality.

However, for the last 1500 years smallpox has been known to be endemic in India, especially in the densely populated agricultural settlements of the Ganges plain. Periodic epidemic episodes occurred then, as they continued to do until the disease was eradicated in the latter part of the 20th century.

#### South-western Asia

Apart from the problematic epidemic among the Hittites, already referred to, the earliest reference to an epidemic disease that may have been smallpox is the description of a plague that afflicted the Ethiopian invaders of Mecca in Arabia in AD 568, in what was called the "Elephant War" (Moore, 1815). The Ethiopian soldiers were afflicted by a severe illness characterized by a rash, which almost totally destroyed the invading army and ended Ethiopian rule in Arabia.

Scholars in south-western Asia and in Alexandria, on the Egyptian Mediterranean coast, produced notable works on smallpox long before European physicians did. Ahrun, a Christian priest who lived in Alexandria 30 years before the Arab conquest of Egypt, wrote clear descriptions of smallpox and measles in AD 622 (Moore, 1815):

"When the smallpox pustules are white and red, they are healthy; when green and black, malignant; and if, after a time, the eruption of smallpox and measles changes to a saffron colour, and the fever moderates, good hopes may be entertained; but if these eruptions appear during a frenzy fever, they are fatal."

The most notable of these writings, however, is that of al-Razi (Abu-Bakr Muhammad Ibn Zakariya, al-Razi (Rhazes)), the great Persian-born physician who was in charge of the hospital at Baghdad. Al-Razi's treatise on smallpox and measles was translated into Latin and Greek and influenced European physicians until the 17th century and even later (al-Razi, 910).

Besides clearly distinguishing between smallpox and measles, as Ko Hung in China had done 6 centuries earlier (see below), al-Razi made some astute epidemiological observations on smallpox, describing its seasonal incidence (most common in spring) and the fact that it was primarily a disease of children.

Another great Persian scholar, Avicenna (980-1037), also wrote on smallpox; translations of his works into Latin influenced medical practice in Europe in Renaissance times.

#### Europe

During the classical era Greece was the only densely populated part of Europe, with a population of about 3 million in 400 BC. By the beginning of the Christian era emigration had reduced the population to about 2 million and the centre of gravity of the population of Europe had shifted to Rome.

There are no unequivocal records of smallpox in Europe before the 6th century AD, but it has been suggested that it was a major component of the "Plague of Athens" that occurred in 430 BC, during the Peloponnesian Wars, and was described by Thucydides. This affliction was said to have originated in "Ethiopia" and spread to Egypt and Libya before crossing the Mediterranean to the port of Piraeus and thence reaching Athens.

### From Epidemics to Endemicity

The earliest writers on smallpox whose descriptions are now universally accepted—Ko Hung in China, Vagbhata in India and al-Razi in Asia Minor—describe smallpox as primarily a disease of children. This is a mark of well-established endemicity and was the result primarily of demographic factors. Alivizatos (1950) noted that smallpox was repeatedly imported into Germany by the Crusaders towards the end of the 12th century. It began to cause extensive epidemics only by the 14th century, eventually becoming a disease in which the majority of cases occurred in children (it was given the name *Kinderblattern*) only at the end of the 17th century. The change occurred more rapidly than this in more densely populated countries (for example in Mexico, see below), but in most places it probably took several human generations. Thus the classical early descriptions of smallpox as a disease primarily affecting children argue for the presence of smallpox in the area concerned (for example in south-western Asia, following al-Razi's description) some centuries earlier.

Except for the absence of any reference to residual pockmarks in those who recovered, Thucydides' description has suggested to several medical historians (Zinsser, 1935; Alivizatos, 1950; Littman & Littman, 1969) that the epidemic may have been due to smallpox. It lasted for over 2 years and devastated the Athenian army.

According to some authorities (Alivizatos, 1950), an epidemic that prevented the Carthaginians from gaining control of Sicily, at the siege of Syracuse in 395 bc, may also have been smallpox. The next speculative suggestion of smallpox in Europe was its possible role in the Antonine Plague, which appeared to start in a Roman army fighting in Mesopotamia in AD 164. Returning soldiers brought an infectious disease to Syria and Italy, where it raged for 15 years and greatly weakened the Roman empire. The clinical features were described, rather inadequately, by Galen, and, more recently, in a critical analysis of the evidence Littman & Littman (1973) argue convincingly that the principal disease that occurred in the Antonine Plague was probably smallpox.

Apart from Rome, there were few centres of population in Europe large enough at that time to have supported endemic smallpox, but various epidemics from the 5th century onwards have been ascribed to the disease. St Nicaise, the Bishop of Rheims, who is said to have suffered from smallpox, was beheaded by the Huns in AD 452 and was later accepted as the patron saint of European victims of smallpox. During the 6th century smallpox may have occurred as an endemic disease with

epidemic episodes, one of which was described by Bishop Gregory of Tours, but Moore (1815) considers that this outbreak was due to bubonic plague. At about this time Bishop Marius of Avenches (near present-day Lausanne, in Switzerland) used the Latin word "variola" for the first time (from *varius* = mottled, or *varus* = a pimple) to describe the epidemic illness then present in Italy and France. It was not until 5 centuries later that Constantinus Africanus first explicitly limited the use of the word "variola" to the disease we call smallpox.

There is a dearth of information on smallpox, as on most subjects, for the remainder of the Middle Ages. However, it undoubtedly accompanied the armies of Islam across North Africa in the 7th century and spread into Spain and Portugal with their conquest in 710. The Germanic warriors crushed the Moors when invasion of France was attempted in 731, but smallpox and measles remained in France as legacies of the Moors. Smallpox may also have occurred from time to time in other parts of Europe following importations from endemic areas, and by the latter half of the 10th century it was a relatively common disease in most of the Arab-controlled areas of North Africa and Europe.

### China and Japan

The earliest agricultural society of China comprised about 1 million peasants dependent on wheat-growing, in the valley of the Huang Ho river in 3000 bc. The population

grew steadily, until by 400 BC there were some 25 million people living in the northern half of China proper, mostly in the valleys of the Huang Ho and Yangtse rivers. After the political unification of China in 221 BC the population grew to about 50 million and fluctuated around that number until AD 1000, when there was a demographic explosion fostered in part by fuller exploitation of the rice-growing potential of the Yangtse valley.

In contrast to the speculations on the existence of smallpox from very early times in Egypt and India, there is general agreement that smallpox was introduced into China from outside the country. According to Needham & Lu (in press), the earliest description of smallpox and its origins in China occurs in the *Handbook of Medicines for Emergencies*, which was completed by the great physician Ko Hung in AD 340:

"Recently some people have suffered from seasonal epidemic sores which attack the head, face and trunk. In a short time they spread all over the body. They look like red boils, all containing some white matter. The pustules arise all together, and later dry up about the same time. If the severe cases are not treated immediately many will die. Patients who recover are left with dark purplish scars the colour of which takes more than a year to fade... People say that it first appeared from the West in the fourth year of the Yung-Hui reign-period, and passed eastwards, then spreading all over the country... Another saying is that in the Chien-Wu reign-period prisoners of war brought it back from Nan-yang, and for this reason one of its names is still 'prisoners' pox'."

Needham & Lu (in press) point out that there are difficulties in giving accurate dates for the periods mentioned in this text, but they conclude that the likely date for the introduction of smallpox was in the years between AD 25 and AD 49, when Ma Yuan was subduing the aboriginal tribal people of Hunan province. Following Hirsch (1883) and Macgowan (1884), Hopkins (1983a) suggests that there may have been an earlier introduction than this, from "Huns" in the north in about 250 BC. If so, as Macgowan suggests, it died out and had been forgotten. From about the 2nd century AD smallpox was established as an endemic disease in the densely populated river valleys; there are references from the latter part of the 6th century onwards to pockmarked persons and to various treatments for smallpox.

Japan consisted of a group of sparsely inhabited islands with a total population of

less than 5 million in AD 1000; most of the islands were too small and too thinly populated to support endemic smallpox. There were nevertheless repeated introductions from China and Korea. As early as the 6th century cultural and trading contacts were increasing between China and Japan, both directly and via Korea. Buddhism was first introduced into Japan from Korea in AD 552, and further contacts were made later that century. Smallpox was introduced at about the same time, and the Japanese were perplexed to know whether to ascribe the pestilence to their indigenous Shinto gods or to the new Buddha. There were repeated reintroductions during the 7th and 8th centuries. Nara, the first real city in Japan, was established in 710; in 735 smallpox, introduced by a shipwrecked sailor, devastated the city of half a million inhabitants and killed many of the nobles. Smallpox continued to be the focus of religious argument between the Shinto priests and the adherents of Buddhism, and in 748 the great bronze statue of Buddha, the *Nara Daibutsu*, was completed, having been commissioned by the Emperor to put an end to his troubles with smallpox. Endemic smallpox was established in Japan during the 10th century, but there were still recurrent severe epidemics that affected villages and towns in which the endemic disease did not occur.

#### Summary: the Spread of Smallpox from Antiquity until AD 1000

It is impossible to do more than guess about the original home of smallpox, which may have developed as a specifically human disease at any time after irrigated agriculture had allowed human populations to grow sufficiently large, perhaps some 6000 years ago. The major contenders for the doubtful honour are Egypt and India. It is reasonable to argue that smallpox was endemic in the densely populated Nile and Ganges river valleys at the beginning of the Christian era. From there it spread west to south-western Asia and made periodic incursions into Europe, but was not properly established around the Mediterranean littoral until the armies of Islam drove through North Africa into the Iberian Peninsula in the 8th century. As population size increased in various parts of Europe, endemic smallpox extended, so that it was probably known throughout south-western Asia and the Mediterranean

littoral of Africa and Europe by the end of the 10th century. Al-Razi published his detailed and perceptive account of smallpox and measles about AD 910.

Early in the Christian era smallpox was carried to the east, first with warring armies and later with traders who moved along the Burma Road in the south and the Silk Road in the north. Smallpox was probably already established as an endemic disease in China by the 4th century, when Ko Hung differentiated between smallpox and measles, some 600 years before al-Razi. Subsequently, as contacts were developed between China and Korea and Japan, smallpox was repeatedly imported into the two latter countries, to become endemic there during about the 10th century.

By the end of the 10th century, therefore, smallpox was probably endemic in the more densely populated parts of the Eurasian land mass and along the Mediterranean littoral of Africa. There were still many uninfected localities, but the stage was set for endemicity with periodic explosive epidemics, a situation that characterized the 16th and 17th centuries in Europe, when this disease then spread to most of the inhabited world. Fig. 5.1 presents a possible scenario of the spread of smallpox throughout the Eurasian land mass and to adjacent countries up to the end of the 1st millennium AD.

## SMALLPOX IN SOUTHERN ASIA BETWEEN 1000 AND 1900

### The Indian Subcontinent

With a population of 25 million by 500 BC, already dense enough in the valley of the Ganges to support endemic smallpox, the population of the Indian subcontinent rose steadily over succeeding centuries to reach about 80 million by AD 1000 and 100 million by 1500. Thereafter it rose somewhat more rapidly, to 185 million by 1800, and then exploded, exceeding 280 million in 1900.

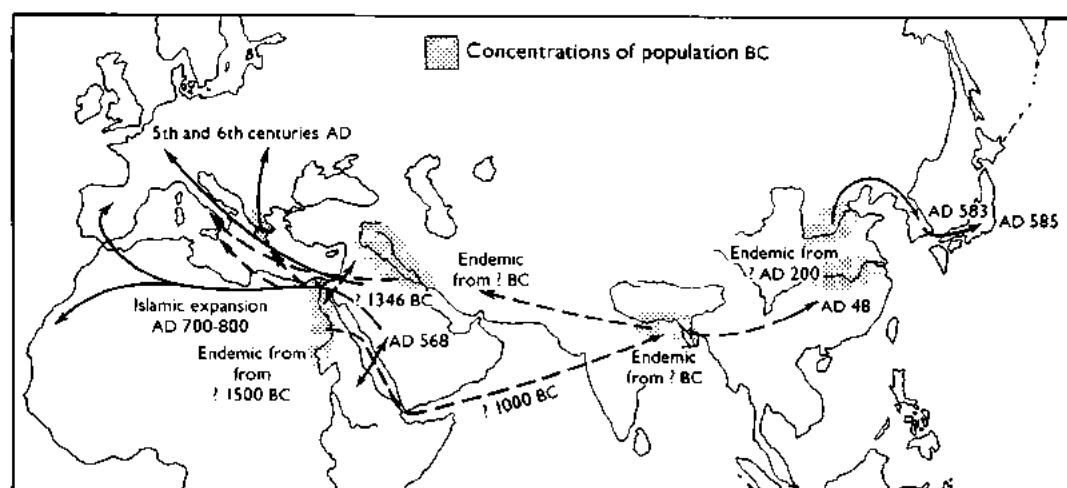

Smallpox was probably present in India for over 2000 years and remained endemic there until its final eradication from the subcontinent in 1975. Apart from the writings of Vagbhata and allusions to the Hindu goddess of smallpox, Śitalā (see Plate 5.2), there is little historical evidence of smallpox in India until after 1500, when European commentators began to report on various aspects of Indian life. The ecological and demographic conditions in India were such that the pattern of endemicity with seasonal (spring) epidemics that was observed after 1500 had probably prevailed for a millennium before that.

The earliest European accounts of smallpox came from the Portuguese enclave of Goa, where 8000 children are said to have

### Inoculation, Variolation and Vaccination

When the practice of deliberately introducing material from smallpox patients into the skin of susceptible subjects was introduced into Great Britain early in the 18th century it was called "inoculating the smallpox" or "inoculation". With Jenner's replacement of material from smallpox patients with fluid from cowpox lesions in 1798, from cows or humans, it became necessary to distinguish inoculating the cowpox from inoculating the smallpox. At first the term "vaccine inoculation" was used; later, Jenner's practice came to be called "vaccination" and the inoculation of material from smallpox patients was called "variolation". In this book we have used the terms inoculation and variolation as synonyms, reserving "vaccination" for procedures involving cowpox or vaccinia virus.

Variolation was always carried out with material from the pustules or scabs of patients. After animal vaccines were introduced during the latter part of the 19th century, vaccination was usually carried out with vaccine "lymph" from cows. However, before that time the virus was maintained by arm-to-arm vaccination of children, and was sometimes shipped over long distances as "vaccine scabs", as well as being dried on threads or ivory points (see Chapter 6).

Fig. 5.1. Possible early sites of outbreaks and routes of spread of smallpox in the ancient world. "Plagues" are historical episodes of epidemic disease reported in ancient and classical literature, which may have been due to smallpox. "Writers" refer to physicians who wrote the principal descriptions of smallpox before the end of the 1st millennium AD.

died in an outbreak in 1545. Scattered references occur to outbreaks of smallpox accompanying military campaigns in Ceylon and on the Indian mainland, but more complete descriptions date from the 18th century, after the beginning of *de facto* British rule in India in 1757.

A decade later, Holwell (1767) described a situation in Bengal which remained characteristic of smallpox in many parts of India during the succeeding 2 centuries: endemic disease with spring (dry season) maxima, punctuated by outbreaks of epidemic intensity every 5-7 years. There were droughts, floods, famine and a particularly severe epidemic of smallpox in Bengal in 1769-1770.

Although variolation had been known for centuries in India, it was nowhere practised on a large enough scale to be of importance as a public health measure. It protected individuals, but its spread from inoculated persons contributed to outbreaks of smallpox. In 1802 the Swiss physician Jean de Carro, who then lived in Vienna and was an enthusiastic supporter of Jennerian vaccination, succeeded in sending viable vaccine to Bombay, via Baghdad. Although at first viewed with

suspicion as a British trick, vaccination spread, initially more rapidly in Ceylon than in India. However, during the first half of the 19th century smallpox continued to take its toll. For example, superimposed on the endemic background were 4 major epidemics in Calcutta during the first half of the 19th century: in 1832-1833, 1837-1838, 1843-1844 and 1849-1850.

During the second half of the 19th century, statistical reports of the occurrence of various infectious diseases were compiled which always ranked smallpox as one of the leading causes of death in India. For example, during the 10 epidemic years of 1868-1869, 1872-1874, 1877-1879 and 1883-1884 (Fig. 5.2), at least 2.5 million out of the estimated 180 million people in British India were reported to have died of smallpox, and experience in the 20th century suggests that there was gross underreporting of deaths as well as of cases. Even in a non-epidemic year, as many as 100 000 deaths from smallpox were reported. Many of the epidemics in India, up to the time of eradication, were intensified by crowding and poverty and the vast movements of people associated with religious festivals,

### Gods, Goddesses and Saints Associated with Smallpox

A feature of human reactions to smallpox that demonstrates its impact was the association of specific gods, goddesses and saints with the disease (Plates 5.2–5.5). Hopkins (1983a) describes these deities and saints in some detail; the characteristics of the best known are briefly noted here.

In Europe, *St Nicaise*, the Bishop of Rheims, who was killed by the Huns in 452, shortly after he had recovered from an attack of smallpox, became the patron saint of smallpox and was revered during the Middle Ages. Subsequently, the Reformation and the greater menace of plague (which threatened all adults as well as children, whereas endemic smallpox was by then mainly a disease of children) led to the neglect of St Nicaise.

*Śītālā (Shitala) mata* appears to have been an Indian folk goddess from early times, whose association with smallpox dates from a later period (Nicholas, 1981). However, from about the 18th century onwards *Śītālā* was closely associated with smallpox and was a widely patronized goddess, with temples and shrines all over India. It will be interesting to see what changes occur in the worship of *Śītālā* now that smallpox has been eradicated from India.

*T'ou-Shen Niang-Niang* was a goddess of smallpox in China. Tradition traces her worship to an 11th century Buddhist nun who is credited with introducing variolation into China (see Chapter 6), and during the mid-19th century she was one of the most popular objects of worship among the people at large, irrespective of their religious affiliations. Temples were erected to her all over China.

In Japan, a red picture of *Tametomo*, a 12th century hero who was reputed to have thwarted a smallpox demon, was often hung in the rooms of smallpox victims to aid their recovery. The colour red had an ancient and persistent association with smallpox, and was supposed to promote recovery (see Hopkins, 1983a).

In Africa, worship of *Sopona*, a smallpox deity, existed among the Yorubas and some of their neighbours in south-west Nigeria, Benin and Togo, having been introduced from the north at the beginning of the 18th century. Formal worship of *Sopona* was controlled by *féticheurs*, who were in charge of the shrines and carried out variolation. Sometimes *féticheurs* were suspected of spreading smallpox. When they were transported to Brazil as slaves, some of the Yoruba-speaking people took *Sopona* with them, although he was more generally known by another of his names from western Africa, *Obaluwaye* ("King of the Earth") or *Omolu*.

famines and wars. Although many adults were attacked, in the majority of cases and deaths the victims were infants and young children. In India at this time, as was the case a century earlier in Europe, there was a popular saying that children should not be regarded as permanent members of the family, for purposes of inheritance, until they had recovered from smallpox. Facial pockmarks were the rule among adults, and blindness, for which smallpox was often responsible, was common.

Against a background of endemic smallpox, a steady succession of major epidemics, peaking every 5–7 years, continued after the great epidemic of 1883–1884 but at a much lower level, because of the cumulative effect of steadily increasing vaccination (see Fig. 5.2). Nevertheless, in many parts of the subcontinent vaccination was not extensively

practised until the 1950s. India and countries adjacent to it remained the major focus of smallpox in the world until 1975, when eradication was achieved there.

### Burma, Siam and Indochina

The population histories of the countries between India and China—Burma, Siam (Thailand) and Indochina (comprising present-day Democratic Kampuchea, Lao People's Democratic Republic and Viet Nam)—are rather similar, although until 1900 the population of Siam was only about half that of the other two. Two thousand years ago the populations of Burma and Indochina each numbered about 1 million (0.5 million for Siam). They had doubled by AD 1000 and doubled again by 1500. By 1800 the popula-

### The Significance of Epidemics

Devastating epidemics of smallpox created a deep impression on the population, and all histories of smallpox are punctuated with lists of the years of the major epidemics. It is important to distinguish two ecologically distinct situations in which such epidemics occurred. The first was when smallpox was introduced into a place in which it had not occurred previously, or at least not for many years, so that a large segment, perhaps all, of the population was susceptible. This led to epidemics that affected all age groups, and because of the great social disruption caused by the simultaneous illness of most of the bread-winners in a subsistence society, such epidemics were associated with very high death rates. In small populations, whether on islands such as Iceland or in the early colonial settlements in North America, the disease finally died out for lack of susceptible subjects. Further epidemics some years later would occur when fresh importations of smallpox encountered populations with adequate numbers of susceptible persons composed of hitherto unexposed children or immigrants.

The second situation in which "epidemic years" were recorded was in populous areas in which smallpox was always present as an endemic disease, as in Europe in the 18th century and the Indian subcontinent until 1975. For a variety of reasons—demographic, climatic and, in later years, the activity of vaccinators—the population of susceptible persons and optimum conditions for transmission fluctuated so that epidemic exacerbations occurred every few years, against a background of endemicity. In this latter situation disruption of the community was much less severe, because there were always many smallpox-immune bread-winners.

tions of the 3 countries were 6 million, 3 million, and 6.5 million respectively; population growth then took off, doubling during the next century.

There is only scanty information on smallpox in these countries prior to the late 19th century. A king of Burma died of smallpox during a military campaign in 1368, and variolation is said to have been introduced into Burma in 1785 from the recently annexed province of Arakan. From the mid-19th century Burma was administered as part of British India, and its smallpox statistics are included in the Indian records (Annual Reports of the Public Health Commissioners with the Government of India).

Siamese writings refer to epidemics of what was probably smallpox during the 14th century, and from the 16th century onwards there are repeated references to *thoraphit* and *ok fi dat* (the formal and familiar Siamese words for smallpox), with severe epidemics in 1563–1564, 1621–1623, 1749–1750 (Terweil, 1987). These Siamese writings were confirmed by the French writer de la Loubère in the late 17th century: "In a word, there are some contagious diseases but the real Plague of this Country is the Small Pox: it often makes dreadful ravages, and then they inter the bodies without burning them" (Loubère,

Fig. 5.2. Reported numbers of deaths from smallpox per million population in British India from 1868 to 1947, and the numbers of primary vaccinations and revaccinations from 1875 onwards. Epidemic peaks occurred about every 5 years throughout this period. (Data from Annual Reports of the Public Health Commissioners with the Government of India.)

reprinted 1969). Vaccination was introduced into Siam in 1840, shipments of vaccine scabs

being sent from Boston, USA, in 1840, 1844, 1846 and 1861, through Christian mission societies.

Severe epidemics continued to occur in Siam and Indochina during the latter part of the 19th century, the mortality among children in some epidemics being so great as to have a prolonged demographic effect because of the paucity of nubile women. As late as 1898, 95% of adolescent children in northern Viet Nam were pockmarked and nine-tenths of all blindness was ascribed to smallpox.

### South-western Asia

Between the Indian subcontinent and Europe lies part of the Eurasian land mass that is variously described as south-western Asia, the Near East and the Middle East. It comprises present-day Afghanistan, Iraq and the Islamic Republic of Iran, the Arabian Peninsula, including its Mediterranean littoral, and Turkey-in-Asia. In 1800 none of these countries had a population of more than 9 million. However, Turkey, Arabia and Persia (Iran) had supported populations of some 4–5 million for the previous 2 millennia, and they were of major importance as centres of culture during the Dark Ages of Europe and as the corridor for trade, culture and conquest between Europe and the Indian subcontinent.

The work of Persian scholars, notably al-Razi and Avicenna, shows that smallpox was endemic in many parts of south-western Asia from at least the 6th century. Early in the 7th century, inspired and united by Mohammed's teachings, Arab armies began their war of conquest and took smallpox with them to Persia, across western Asia and northern Africa and into Spain, which was conquered in 710.

Although by the time they had reached adult life most persons would have been immune to the disease, smallpox affected several of the rulers of the Arabian empire, killing one caliph, leaving three with pockmarks and blinding two others. In the 10th and 11th centuries, as Arab traders extended their voyages to the east coast of Africa and across the Sahara to western Africa, their expeditions introduced smallpox into Africa south of the Sahara (see below).

Variolation by cutaneous inoculation was practised in various parts of south-western Asia from early times. It is said to have been introduced into Egypt by the Mamelukes in the 13th century, and it was in Constantino-

ple that Lady Mary Wortley Montagu and the physicians Emanuele Timoni and Jacob Pylarini learned of the procedure in the early 18th century (see Chapter 6). However, it does not appear to have been practised on a scale or in a way that mitigated the severity of smallpox in the community, although it was important in preserving the beauty of recruits to the imperial harems.

### SMALLPOX IN EASTERN ASIA BETWEEN 1000 AND 1900

#### China and Korea

The population of China, which had remained at 50–60 million for the whole of the 1st millennium of the Christian era, doubled during the next 2 centuries as the rice-growing potential of the Yangtse valley was further exploited. Then in 1211 the Mongols began their conquest of China, a bloody war which killed some 35 million people. It was 1500 before the population reached the level (110 million) that it had attained 300 years earlier. Thereafter population growth surged ahead, apart from a set-back in the middle of the 17th century associated with the Manchu conquest, and by 1900 the total number of inhabitants had reached about 475 million.

Smallpox spread through the dense agricultural settlements of the Huang Ho valley and from about the 2nd century AD was established as a major endemic and epidemic disease in China and Korea. As early as the 4th century Ko Hung had written a good clinical description of smallpox (see above), and in the 11th century medical descriptions of smallpox were published by Ch'ien Chung-Yang (1040–1121), who popularized the modern Chinese character for smallpox (a combination of the characters for "lentil-bean" and "sickness"). At about this time worship of a goddess of smallpox, T'ou-Shen Niang-Niang (Plate 5.4A), began. Buddhist, Taoist and Confucian adherents paid tribute to the "Dame who controls smallpox", who was feared more than she was loved.

Although preventive inoculation (variola-tion) was probably introduced into China at about this time it appears to have been practised as a secret rite and on a small scale (see Chapter 6). It became a public practice during the first half of the 16th century (Needham, 1980), but was never widely used.

At the beginning of the 13th century China had a population of about 100 million, and

smallpox was established in the densely populated areas as an endemic disease, affecting mainly children. It was seen as a threat by the tribal peoples to the north. The Mongols, for example, who began their invasion of China at this time, regarded contacts with the Chinese as a grave danger, whether at horse fairs or in border raids. Four centuries later the leaders of the Manchus dreaded smallpox. In planning raids through weak spots in the Great Wall in 1633, the Manchu Khan insisted that only officers who had had smallpox should be sent on these expeditions, since they would have to go through populations in which smallpox was endemic. When the Manchu dynasty was later established, care was taken to exempt both Manchus and Mongols from otherwise mandatory appearances in Peking (see box). Perhaps, as Manchus, they did not trust variolation; at all events, in 1661, the Shun-Chih Emperor, Aihsin-Chuch-lo Fu-lin, died of smallpox. The third son, the pockmarked K'ang-Hsi (Plate 5.3C), was chosen to be his successor precisely because he had already had smallpox; he reigned as Emperor of China from 1661 to 1722 (Spence, 1974). Unlike earlier Manchus, K'ang-Hsi had his regular troops inoculated against smallpox "as I did my own children".

Late in the 18th century the Tibetan leaders, the Dalai and Panchen Lamas, for a long time declined invitations to come to the court in Peking because of their fear of smallpox. In 1780 the Panchen Lama acceded to the invitation of Emperor Ch'ien-Lung, only to die of smallpox within a few weeks of his arrival. From this time onwards, variolation and, later, vaccination played increasing roles in the epidemiology of smallpox in China, but towards the end of the 19th century European visitors noted that it was difficult to find an adult Chinese entirely free from pockmarks and that persons blinded by smallpox were still very common.

Vaccination was first introduced into Canton and Macao in 1805 by the famous Balmis-Salvany Expedition organized by King Carlos IV of Spain (see Chapter 6). However, the practice was not readily adopted and only spread at all widely in China during the latter half of the 19th century. Indeed, vaccination in China was totally inadequate until the campaign mounted in 1950.

Epidemics of smallpox of great severity ravaged Tibet until 1940, when vaccination was first introduced. Smallpox is thought to

have contributed significantly to the declining population of Tibet in the early 20th century.

## Japan

The Japanese state came into being in about AD 650, when the population of the islands had reached approximately 3 million. Thereafter the population grew steadily—to 4.5 million in 1000, 9.75 million in 1300, 22 million in 1600 and about 30 million in 1700. There was then a check in population growth for a century and a half, with an explosion after 1850, when Japan was opened up to Western shipping and Western ideas, so that by 1900 the population had reached 45 million.

Smallpox had been repeatedly introduced into Japan from China and Korea ever since AD 585. At first it died out after each introduction but by the 10th century the disease was endemic. Numerous outbreaks occurred throughout the 10th century, with major epidemics recorded in the years 915, 925, 947, 974, 993 and 998. In 982 the "red treatment" (see box) was first described in *Ishinbo*, a Japanese medical book. This practice later spread around the world and persisted in Europe and the USA down to the 20th century, as described by Hopkins (1983a). *Ishinbo* also makes mention of special isolation hospitals for smallpox patients, several hundred years before the London Small-Pox and Inoculation Hospital was established in 1746.

During the 13th, 14th and 15th centuries Japan recorded 7 widely spaced epidemics of smallpox (1209, 1277, 1311, 1361, 1424, 1452 and 1454). Only 2 epidemics were recorded in the 16th century (1522 and 1550), but in the 17th century the country was more severely afflicted by outbreaks, during which the Japanese royal family was affected. The northern island of Hokkaido recorded an average of 1 epidemic of smallpox every 14 or 15 years during the 17th and 18th centuries.

At the end of the 17th century the Japanese distinguished 4 types of pox-like illnesses: *fooso* (variola), *fasuka* (measles), *kare* (chickenpox) and the "Portuguese disease" (syphilis) (Kaempfer, 1906). Strangely, the Japanese remained ignorant of the value of variolation until it was introduced from China in the mid-18th century, and as its population density increased Japan continued to suffer heavily from smallpox. Eventually, after

### Customs of Mongols, as Affected by Smallpox

"From hereon, Mongols from the Inner Administration [i.e., Inner Mongolia] and from the Qalqas who are to inherit a rank, and have reached (legal) age [18 years], if they have once contracted smallpox, shall come to the capital to be installed, presented at court, and receive their succession. Those who have not yet contracted smallpox, shall proceed to Jehu [= Jehol, north of the Great Wall] to be installed, appear at court, and receive their succession." (Edict, 1784, quoted by Serruys, 1980.)

several unsuccessful attempts, vaccination was introduced into Japan in 1849, using crusts from vaccination lesions imported from the Netherlands East Indies. Between 1850 and 1860, smallpox vaccination clinics were opened all over Japan, and their success helped to erode the Japanese inhibition about Western learning. Smallpox epidemics continued, however, and there were several severe outbreaks in 1870. A new vaccine institute was established in Tokyo in 1874, and a compulsory vaccination act was promulgated in 1876.

Most accounts of the mortality associated with smallpox in the days before vaccination was available relate to statistics gathered in large cities. Suda & Soekawa (1983) have now provided a fascinating account of the impact of smallpox in rural Japan in the 18th and early 19th centuries. In 1795 a "virgin-soil" epidemic occurred in the village of Mine, on Hachijo-jima, a small island south of Honshu. There were 1200 cases in a population of 1400 persons (85.7% morbidity) with 460 deaths (a case-fatality rate of 38.3%).

Using temple records, Suda & Soekawa were able to compute the smallpox mortality in the mountainous Hida district on Honshu Island, between the years 1771 and 1851. Smallpox was endemic in the district and neither variolation nor vaccination was practised. The smallpox mortality, as a percentage of total mortality in the whole population and in children under 5 years of age, is shown in Fig 5.3. Although the data relate to mortality, it is reasonable to assume that this reflects the morbidity. The periodicity of outbreaks is obvious, due presumably to the decrease and subsequent increase in the number of susceptible persons, with the periodic disappearance and reintroduction of smallpox. The brunt of the mortality was borne by children under 5 years of age, who constituted about 11% of the population but suffered well over 50% of the deaths from smallpox in epidemic years. In spite of the mortality due to smallpox, the population rose slowly from 2677 (calculated) in 1771 to 3127 (calculated) in 1851.

Fig. 5.3. The mortality from smallpox in the Hida district on Honshu Island, Japan, from 1771 to 1851. The population of the district rose from 2677 in 1771 to 3127 in 1851 (lowest 2535 in 1786; highest 3132 in 1834). The solid line indicates deaths due to smallpox as a percentage of all deaths. The broken line (and higher percentage figures) indicates deaths due to smallpox as a percentage of all deaths in children under 5 years of age. The total number in this age group rose from 310 in 1771 to 439 in 1851 (lowest 234 in 1838; highest 444 in 1850). (Data from Suda & Soekawa, 1983.)

### The Red Treatment

*Ishinbo* was probably the first book to mention the existence of red cloth hangings in the rooms of smallpox patients. The practice persisted and in the 17th century a European doctor reported that Japanese physicians "... think it very material in the cure of smallpox to wrap up the patient in red cloth. When one of the Emperor's children falls sick of this Distemper, not only the room and bed are furnished with red; but all persons that come near the patient must be clad in gowns of the same colour" (Kaempfer, 1906). Red paper and red cloth were also hung around the beds of children with smallpox in China, India, Turkey and Asian Georgia; even in western Africa, the Yoruba god of smallpox, Sopoṇa, was associated with the colour red.

In European countries the red treatment was practised from the 12th century onwards, and when he caught smallpox, King Charles V of France (reigned 1364-1380) was dressed in a red shirt, red stockings and a red veil. Queen Elizabeth I of England was likewise wrapped in a red blanket when she fell ill with smallpox in 1562, and similar treatments were applied to other European monarchs.

The red treatment was given scientific authority by Finsen, who claimed that the treatment of smallpox patients with red light reduced the severity of scarring, and later developed rules governing erythrotherapy (Finsen, 1901). It lingered on into the 1930s, although Ricketts & Byles (1904), Schamberg (1904) and others had declared it to be useless.

### Indonesia and the Philippines

Two thousand years ago rice-growing Malay peasants were concentrated on the island of Java and the total population of the Malay Archipelago was about 2 million. Wet rice cultivation was introduced from India in about the 4th century and the population rose to 4 million by 1000 and 8 million by 1500. It continued to increase slowly until the European domination of the islands early in the 19th century, when the population soared from about 12 million in 1800 to 38 million in 1900.

The Philippine islands were even more sparsely populated initially, with only a few hundred thousand inhabitants by 1000, rising to half a million by 1500 and just over a million during the 17th century, when the islands were conquered by Christian Spaniards and Muslims from Indonesia. Thereafter, the population grew more rapidly, reaching 2.5 million by 1800 and 8 million by 1900.

Because of the frequent trading contacts between India and the larger islands of the Malay Archipelago from the 4th century onwards, there were repeated opportunities for the introduction of smallpox, but initially population concentrations were too small for the disease to become endemic. The Philip-

pines were in frequent contact with China, but their population was even more sparse.

No written accounts of smallpox in the Philippines and Indonesia are available until the explorations of the Portuguese and Dutch seafarers in the 16th century, who reported that the disease was then known in both the archipelagos, but was endemic only on the larger islands. Elsewhere, importations of smallpox caused greatly feared epidemics, which occasionally originated from far away, as, for example, when a ship from Mexico carried smallpox to the Philippines late in the 16th century. Severe epidemics were reported in Sumatra in 1780-1783 and in Sarawak, on the island of Borneo, in the following century.

Vaccine virus arrived in Java from Mauritius in 1804, and vaccination was employed from 1816 onwards. However, supplies often failed because regular arm-to-arm vaccination was not begun until 1856. A central vaccine institute was established in Jakarta at the end of the 19th century.

Further north, smallpox was recorded in Penang in 1805, and was introduced into Singapore shortly after it was founded in 1819. Because of commercial traffic with India and China, Singapore, while too small to maintain endemic smallpox, was subject to repeated epidemics due to importations, with notable outbreaks in 1838, 1849-1850, 1859-1860, 1899-1900, 1902-1903 and 1910-1911.

## SMALLPOX IN EUROPE BETWEEN 1000 AND 1900

Smallpox had occurred in Europe as an occasional epidemic following importations before the end of the 1st millennium of the Christian era, by which time it was established as an endemic disease on the southern and western fringes of the continent, but not in central and northern Europe. The movement of European Christians to and from south-western Asia in the course of the Crusades during the 11th and 12th centuries helped to spread smallpox in Europe, and "entirely unambiguous" statements about the prevalence of smallpox in Europe date from that time (Hirsch, 1883). Some dramatic episodes were recorded shortly after this; for example, in 1241 the first epidemic among the "virgin-soil" inhabitants of Iceland killed some 20 000 of its total population of about 70 000, to be followed by other severe epidemics in 1257 and 1291.

The steady growth of population in Europe, particularly in the north-west, from a low figure of about 26 million in the 8th century to some 80 million by the beginning of the 14th century, was interrupted by the Black Death, which reduced the population by more than 25%. Thereafter, it began to increase steadily again—from 80 million in 1500 to 100 million by 1600—but there was a set-back in 1620–1650 associated with the Thirty Years War and several severe outbreaks of plague. The 18th and early 19th centuries saw very rapid population growth from 140 million in 1750 to 250 million by 1845.

By the 15th century smallpox had become endemic in many parts of Europe and was recorded as a disease of children in Paris. However, it does not appear to have been quite as severe as it became in the 17th and 18th centuries. Reasonably good mortality records are available for Italy and Spain at this time, but they give little prominence to smallpox (Carmichael, 1983). Perhaps the strains of virus then circulating, although not as mild as variola minor as seen in the 20th century, were somewhat less virulent than classical variola major. Endemicity was not established in the outlying islands and both Iceland and Greenland occasionally suffered epidemics that caused numerous deaths in all age groups (Steffensen, 1977).

At the end of the 15th century venereal syphilis was recognized as a "new" exanthematous

disease, which the French called "*la grosse vérole*" to distinguish it from variola, which became "*la petite vérole*". The English followed suit; "pox" becoming the "small pox" and syphilis the "great pox"—the epithet "great" denoting the larger size of the primary and tertiary lesions and, in addition, conveying the notion that it affected adults whereas smallpox was largely a disease of children.

By the 16th century smallpox was well established over most of Europe, except possibly Russia, and as the population increased and became urbanized epidemics occurred more and more frequently, and were better recorded, especially when they affected the royal houses of England, France and Spain. For the first time, important scientific works on infectious disease emerged from Europe, and Girolamo Fracastoro's classic treatise on communicable diseases, *De Contagione et Contagiosis Morbis*, was published in 1546. He noted that diseases such as smallpox were specific contagions that could spread from person to person directly or via fomites, or even through the air. He also commented on the fact that smallpox was primarily a disease of children, as had al-Razi 600 years earlier. In Spain, the presence of smallpox at this time was of particular importance because it provided the source of the shipboard infections that the conquistadors were to spread to the New World.

The 17th century was a period of turmoil in Europe, with constant military activity, the rapid growth of cities and the burgeoning of intellectual activities in the urban class. Academies were established and scientific journals published. Smallpox succeeded plague, leprosy and syphilis as the continent's foremost pestilence. The great English physician Thomas Sydenham (1624–1689), like Ko Hung and al-Razi long before him, clearly distinguished smallpox from measles and observed the different prognoses of patients with confluent and discrete smallpox rashes. A pandemic of smallpox that swept much of Europe and the Near East in 1614 was important because it was probably responsible for the first importation of smallpox into the English and French colonies in North America. At this time also smallpox was established in Russia and was soon carried from Moscow to Siberia, where devastating epidemics occurred in previously unexposed populations.

Fig. 5.4. Deaths from smallpox per 1000 deaths from all causes in London, from 1629 to 1900. (Data from Guy (1882) and the Registrar General's Statistical Review of England and Wales.)

An important innovation at this time was the introduction of statistical records. Parishes in London began registering church burials by cause of death, and from 1629 onwards "Bills of Mortality" were published in London (Fig. 5.4).

The authorities in Geneva had started keeping records of deaths from smallpox by age groups from 1580 (Perrenoud, 1980), and in 1680 the Tsar initiated a reporting system in Moscow. From this time onwards, also, the infection of members of Europe's royal houses

had dramatic effects on the succession in several countries, a feature of smallpox in history that is well described by Hopkins (1983a).

Even greater devastation occurred during the 18th century, affecting the general population and royalty alike. The London Bills of Mortality, incomplete though they were, record the increasing impact of smallpox in England (Fig. 5.4). Severe epidemics occurred in Paris in 1719 and 1723, and in the 80 years before 1775 smallpox killed Queen Mary II of England, Emperor Joseph I of Austria, King

Luis I of Spain, Tsar Peter II of Russia, Queen Ulrika Eleonora of Sweden and King Louis XV of France; this doubtless influenced royalty in several countries to promote the practice of protective inoculation (variola-tion). By the middle of the 18th century variolation was having an ameliorating effect on the mortality of smallpox among the well-to-do in Great Britain, the Netherlands and Switzerland. As with vaccination in later centuries, its popularity waned when smallpox was less common and was revived by epidemics, such as the large epidemic in Great Britain in 1752. Variolation remained unpopular in France, Italy, Spain and Sweden, all of which experienced severe outbreaks. In Russia, however, Catherine II, affected no doubt by the experience of smallpox in her own household and by the tragedies in the Hapsburg families, commissioned an Englishman, Thomas Dimsdale, to inoculate her and thus popularized variolation in Russia, which was still suffering from recurrent severe epidemics of smallpox, especially in Siberia and Poland.

The effects of smallpox during the latter part of the 18th century can be appreciated by an examination of the data assembled by Hopkins (1983a). During the last 2 decades of the 18th century, smallpox killed over 36 000 persons in London, and an equal number in Glasgow. This constituted almost 1 out of every 10 deaths in London, and nearly a fifth of all the deaths in Glasgow in that period. In British towns, 9 out of every 10 persons who died of smallpox were under 5 years old.

Smallpox was always present in Great Britain's densely populated large cities, even between epidemics, whereas in the more sparsely populated countryside it commonly appeared only in epidemics, separated by smallpox-free intervals of several years. For young adults from these rural areas who had previously escaped infection, smallpox was one of the most serious risks they faced in the big cities.

In continental Europe also, smallpox was still very destructive. In Sweden, major epidemics in 1779 and 1784 killed over 27 000 persons in those two years alone. Rosen von Rosenstein, a Swedish physician, reported that smallpox killed 10% of all Swedish infants each year. In Russia, Sir Alexander Crichton, the Tsar's British physician, reported that one-seventh of all Russian infants died of smallpox each year. And in France also, de La Condamine claimed that 1 out of every 10

persons born in that country died of smallpox. Berlin recorded 6 smallpox epidemics between 1766 and 1795, each of which carried off about 1000 inhabitants. The Berlin epidemic of 1795 was thought to have been initiated by spread from freshly inoculated persons, and epidemics in Weimar (1788) and Hamburg (1794) were attributed to the same cause. In Vienna, over 16 000 persons were infected during an outbreak in 1790, of whom about 1500 died. Iceland had epidemics in 1707 and 1786.

In 1796, the year of Jenner's discovery of the protective value of cowpox, smallpox killed over 3500 persons in an epidemic in London. Throughout Great Britain and Ireland, the disease claimed an estimated 35 000 more lives that year. In the German states, over 65 000 deaths were attributed to it. Europe (excluding Russia) was losing over 400 000 citizens each year through deaths from smallpox, which also was responsible for more than a third of all the cases of blindness in Europe.

With Jenner's publication of his discovery of the protective effect of inoculation with cowpox virus (see Chapter 6), vaccination spread with remarkable speed, in sharp contrast to the slow adoption of variolation in most European countries. It was soon practised on such a large scale that it altered the pattern of smallpox, the incidence of which declined and remained at relatively low levels for the first few decades of the 19th century (Fig 5.4). Such epidemics as did occur were less severe. In Sweden extensive vaccination reduced the number of reported deaths from smallpox from about 12 000 in 1800 to 11 in 1822 (see Chapter 6, Fig. 6.1), and in Denmark not a single case was recorded between 1811 and 1818. Nevertheless, an estimated 8 million Russians suffered from smallpox between 1804 and 1810, of whom 827 000 died. In addition to epidemics in various European cities, smallpox pandemics occurred in 1824-1829 and 1837-1840 which affected nearly all of Europe. The reasons for this resurgence were complex. At that time vaccination was a cumbersome procedure involving arm-to-arm inoculation, and, with the lower incidence of smallpox, enthusiasm for vaccination declined. Another reason was probably the failure to appreciate the fact that a single vaccination did not give lifelong protection. This problem was overcome when revaccination was introduced in Germany in 1829, although it was not adopted by the

British army until 1858 and by the civilian population much later than that.

The Franco-Prussian War of 1870–1871 was associated with severe outbreaks among the poorly vaccinated civilians of France and Prussia (Prinz, 1916). The Prussian army of 800 000 men, revaccinated every 7 years, suffered only 8463 cases of smallpox, with a case-fatality rate of 5.4%, whereas in the unvaccinated French army there were 125 000 cases, with a case-fatality rate of 18.7%. As expected, smallpox spread beyond the belligerent states to the rest of Europe, and it was estimated that at least half a million Europeans died of smallpox in the pandemic triggered by the Franco-Prussian War (Rolleston, 1933). One consequence was legislation to enforce vaccination and revaccination in many countries of Europe, but in some countries these efforts were countered by violent antivaccination movements—notably in Great Britain—based primarily on the principle that compulsory vaccination was an infringement of personal liberty. The century closed with smallpox still endemic in every country of Europe, but with more hope for the future because of improvements in vaccine quality and production methods and in the public health infrastructure.

### THE SPREAD OF SMALLPOX BY EUROPEAN EXPLORERS AND COLONISTS

Up to about the 15th century smallpox appears to have been confined to the Eurasian land mass and a few adjacent countries: those of northern and western Africa and the Horn of Africa, Japan, and Ceylon and the Malay and Philippine archipelagos. Arab traders and slave-traders had introduced it into the coastal areas of eastern and western Africa, but most of central and southern Africa was probably free of the disease. The great explorations and subsequent migrations of Europeans to the Americas, Africa and Australia in the 15th–18th centuries opened up those entire continents to the fatal impact of the advanced technologies and infectious diseases of Europe. Some European conquests owed a good deal of their success to the effects of disease on the indigenous peoples, especially smallpox in the Americas. Fig. 5.5 illustrates the pattern of introductions of smallpox to continents outside the Eurasian land mass. Subsequent sections of this chapter elaborate on the history of smallpox in these newly invaded continents—Africa, the Americas and Australia.

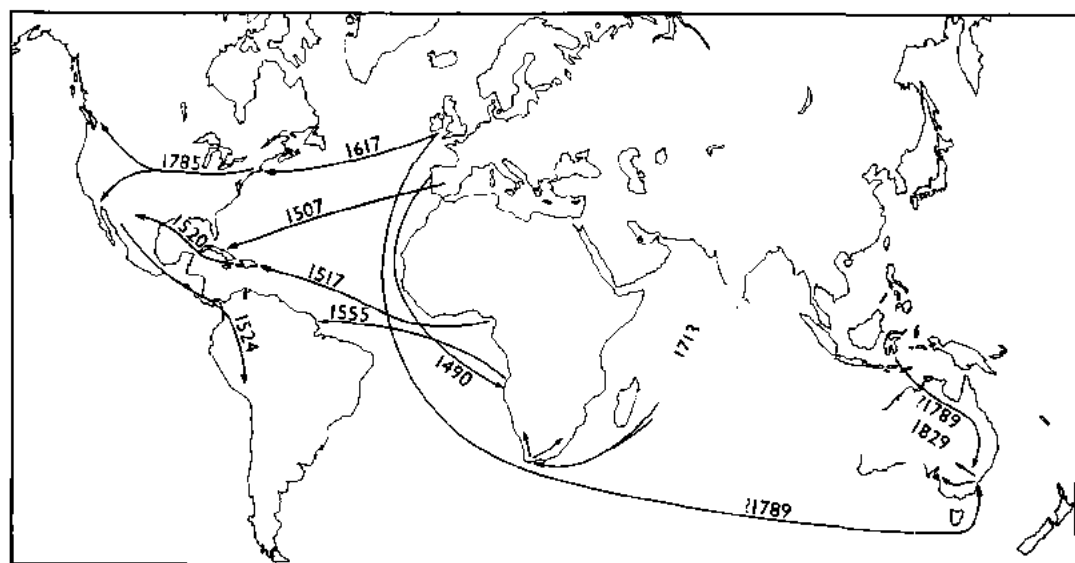

Fig. 5.5. The spread of smallpox to the Americas, South Africa and Australia with European exploration and colonization. It is not known whether the outbreaks among Australian aborigines in 1789 were caused by the transmission of the disease by ship from Great Britain or spread from islands of the East Indies to northern Australia.

## SMALLPOX IN AFRICA BETWEEN 1000 AND 1900

The vast continent of Africa is relatively sparsely inhabited now, and its population was far smaller a thousand years ago. The desert area of the Sahara, then as now, separated the countries of the Mediterranean littoral and the Nile valley state of Egypt from sub-Saharan Africa, in which the great rain forests of the Niger and Zaire basins and the Kalahari desert in the south were largely uninhabited (Fig. 5.6).

Africa is racially and culturally complex. By AD 1000 the Bantu-speaking Negroes, who originated in western Africa, had spread throughout central and eastern Africa and were probing southwards. The aboriginal inhabitants of central and western Africa were reduced to a minority living in the dense tropical forests, and the Bushmen were confined to southern Africa and the Kalahari desert. The population south of the Sahara probably numbered about 30 million, mostly Negroes.

In the north the earliest presumptive evidence of smallpox anywhere in the world is in Egyptian mummies, over 3000 years old. Later, smallpox swept along the North African coast at the time of the great expansion of Islam in the 8th century, and from that time onwards remained endemic in these Mediterranean lands.

Apart from areas of western Africa near the Gulf of Guinea, the mediaeval African countries developed in the interior of the continent, in the grasslands south of the Sahara, the central uplands of the Rift Valley and south to Zimbabwe. Commerce between Egypt and the north-eastern countries (present-day Ethiopia, Somalia and the coastal part of Kenya) and the countries of south-western Asia to the north was active from ancient times. One of the earliest records of a pestilence that may have been smallpox was, as already noted in this chapter, associated with the "Elephant War" in AD 568, when Ethiopian troops besieged Mecca and were decimated by disease, which they carried back to Africa.

Since there were Arab colonies in the port towns along the eastern African coast as far south as Mombasa, and Arabs traded as far afield as India and China, it is likely that smallpox was periodically imported into these coastal towns, perhaps as early as the 13th or 14th century. But no written records are available earlier than those of the 16th

century, when Portuguese traders replaced Arab merchants. The coastal towns were sometimes raided by tribes from the interior, and in 1589, after one such raid along the coast of Kilwa and Mombasa, a severe epidemic of smallpox affected all age groups among the African inhabitants but spared all the Portuguese except the young children.

The populous countries of western Africa were connected by caravan routes to Nubia and Ethiopia in the east and the countries of the Mediterranean littoral to the north. After the arrival of Islam in the 11th century, trading relationships were strengthened and pilgrims travelled to Mecca. It is likely that smallpox was introduced into some of these relatively densely populated western African kingdoms from the 11th century onwards, but there are no European records about smallpox in western Africa until the 17th century, when the disease was apparently widespread, variolation appears to have been practised, and a god of smallpox was an established member of the indigenous pantheon of some tribes (Plate 5.5). Smallpox had probably been endemic there for some centuries, many years before the slave trade to the Americas was established in the 16th century.

The slave trade provided excellent conditions for spreading smallpox, and since raiders penetrated deep into the interior the overland caravans carried the disease far and wide in central Africa. No contemporary records exist of these incursions, but later European explorers recorded the devastating effects of smallpox that they found along every caravan route. Those who failed to contract smallpox on the trek to the coast were liable to be infected while awaiting shipment or on board ship, and there are numerous records of smallpox at the coastal camps and in the slave ships during the 17th and 18th centuries. Indeed, such shipments were a perceived threat to the colonists in the Americas. On the east coast, also, slave ships carried smallpox, as recorded in 1729 in a ship travelling from Madagascar to Réunion.

The Portuguese established a settlement at Luanda, Angola, in 1484, and probably introduced smallpox into the area shortly after that. Over the next 2 centuries smallpox and the slave trade combined to take a terrible toll of the population.

Southern Africa was free of smallpox when the Dutch settled in Cape Town in 1652. At this time the only indigenous inhabitants were Bushmen and Hottentots, but the Ban-

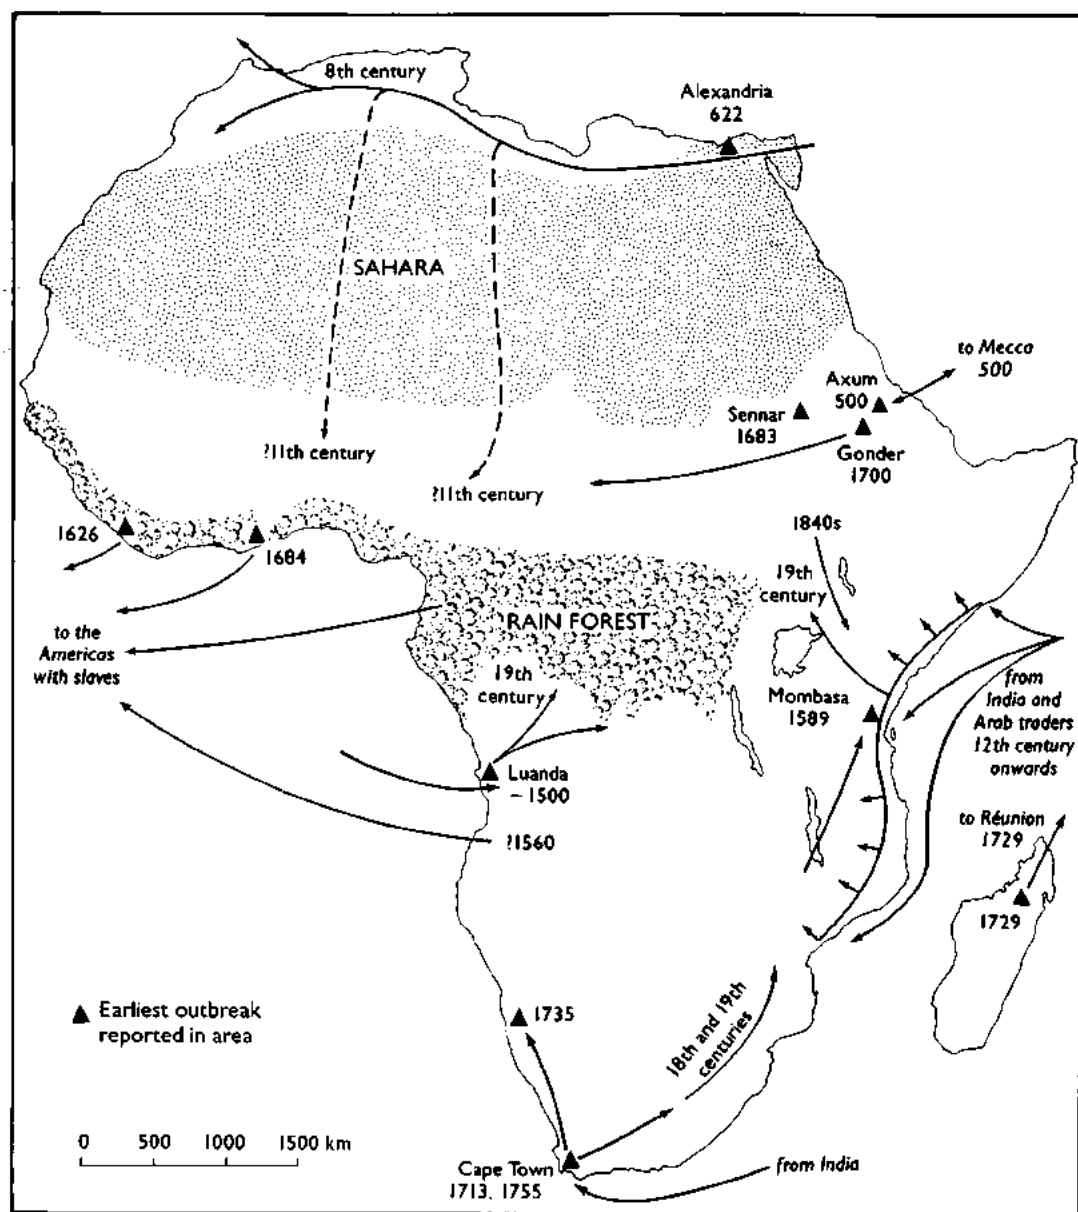

Fig. 5.6. Spread of smallpox to Africa and within the African continent. Endemic smallpox was established in the Maghreb during the Islamic conquests in the 8th century and probably spread from there along the trade routes across the Sahara to the dense populations of western Africa during the 11th and 12th centuries. Further south in western Africa smallpox was not imported until the Portuguese occupation in the 15th and 16th centuries. Thereafter it was exported from western Africa to the Americas. On the eastern coast, smallpox was imported periodically from India via Arab and Indian traders. Another focus was established in southern Africa after importations in 1713 from India and 1755 from Ceylon. The interior of the continent was probably smallpox-free until the 19th century. (Based on Hopkins, 1983a.)

tus were already migrating southward from Zimbabwe. In 1713 smallpox was imported into South Africa with a ship that was returning from India and docked at Cape Town. Although there were no active cases aboard, the virus was taken ashore in laundry.

In the ensuing outbreak the white population suffered severely, nearly every family being affected. Many of the Dutch adults were immune because of smallpox contracted during their childhood, but the Hottentots were totally susceptible, and very large numbers of

them died, whole clans being wiped out. Smallpox did not become endemic, however, and a second outbreak followed an importation into Cape Town from Ceylon in 1755. Again, although the whites suffered severely, with over 1000 deaths between May and October, the Hottentots were even more severely devastated. The disease spread among the Hottentots and Bushmen as far as the Kalahari desert, and wiped out several Hottentot tribes. Yet a third outbreak occurred in 1767, introduced on this occasion by a Danish ship from Europe. The European settlers had by this time learned of the value of variolation and suffered only 179 deaths among some 2000 cases, but the remnants of the Hottentots and the Bantu tribesmen, who were by then in the vicinity, suffered much more severely.

Although the Atlantic slave trade was curtailed from the early 19th century onwards, Arab slavers continued to operate in eastern Africa and carried smallpox from Mozambique to Cape Town in 1812, and to Mauritius in 1840. Slave ships intercepted by the British navy sometimes brought smallpox into African ports then free of the disease—as occurred in 1840, when a captured slave ship brought smallpox again to the Cape Colony, starting another outbreak, which killed over 2500 of the inhabitants.

In the 19th century the Arab slave trade expanded from the east coast ports into central Africa. Smallpox was brought into Uganda by slave caravans in the 1840s. Although there may have been earlier introductions by ivory hunters, the populations were too sparse to support endemic smallpox. The increased commerce and population movements of the 19th century thus brought smallpox to hitherto unaffected populations, on which it wrought extreme havoc. Mortality rates of 80% were reported among the Griqua people in 1831, and as late as 1899 smallpox almost exterminated some tribes in northern Kenya. A similar pattern was observed as central Africa was opened up to European trading from the west, and some parts of the eastern Zaire river basin were completely depopulated.

In the meantime smallpox continued to be a severe endemic disease in coastal towns and in northern Africa. In addition, 6 epidemics were recorded in Ethiopia and the Sudan in the 19th century—in 1811–1813, 1838–1839, 1865–1866, 1878–1879, 1885–1887 and 1889–1890. In western Africa, also, smallpox

continued to take a toll of lives and to affect military campaigns, as in the Ashanti Wars in the 19th century. In Angola, an epidemic that started in 1864 affected about one-third of the Angolan population, killing over 25 000 persons, and helped to shift the balance of population towards the south.

"The variola epidemic by mid-1864 was on the rampage. It spread inland to the east with many caravans of trade, and spread south along the coast by contact with vessels in the ports. Two of the most famous explorers of Central Africa residing in Angola died as a result of this epidemic in 1864 . . . The negroes fled in all directions to avoid the epidemic . . . entire populations would migrate from their villages . . . Luanda was on the verge of anarchy as people died in great number . . . Great quantities of wax, ivory, gum, and copper, indeed the sinews of trade, stayed in piles along the roads and paths or abandoned in heaps at such inland stations as Malanje." (Wheeler, 1964.)

Variolation antedated European colonization of western Africa. It was practised in southern Africa from the mid-18th century and was known in all regions of Africa from the early 19th century (see Chapter 6), but nowhere was it used as a method of protecting communities—only individuals. In some parts it was feared as a mechanism for the spread of smallpox, especially in western Africa, where the *féticheurs*, who by tradition carried out the inoculations, stood to profit from the practice.

Finally, the earliest accounts of a mild form of smallpox, now called variola minor, are those describing "kaffir-pox", or "amaas", in South Africa (see Chapter 6).

### SMALLPOX IN THE AMERICAS BETWEEN 1507 AND 1900

The Americas were first colonized by migrants from Asia who crossed the northern land (ice) bridge over the Bering Strait some 20 000 years ago. Before Columbus "discovered" America in 1492 these people had spread throughout both North and South America, to the very southernmost tip of the continent in Tierra del Fuego. Two thousand years ago the total population of the Americas was probably about 5 million; it had doubled by AD 1000 and reached approximately 25 million by 1500. In Mexico the Aztec empire embraced an estimated 8 million subjects, somewhat more than did the Inca empire in Peru. Tenochtitlán and Cuzco were great cities, with large populations. Along the

eastern seaboard of North America, in the Caribbean, in southern Mexico and Central America, Venezuela, Colombia and northern and eastern Brazil, there were semi-agricultural tribes who added another 5 or 6 million to the continental total. In addition, there were about 3 million hunters and food-gatherers roaming the immense and empty lands of central and western North America, the tropical jungles of Brazil and the desolate wastes of southern Argentina (Fig. 5.7).

These large populations, city-dwellers and agriculturists alike, were free of the familiar communicable diseases of Europe. When smallpox was introduced into Mexico and Brazil by the Spanish and Portuguese invaders and into North America by the British and French, its impact was catastrophic. Since these episodes differed in many respects it is convenient to consider them separately.

### The Spanish and Portuguese Colonies

The first occurrence of smallpox in the Western Hemisphere was on the island of Hispaniola in 1507, following an importation from Spain. The epidemic which followed exterminated whole tribes, but eventually died out. Most subsequent importations into the Caribbean islands, Mexico and Brazil were associated with the African slave trade, which began in about 1503. In 1517 an outbreak occurred among African slaves in the mines of Hispaniola and spread rapidly to the Amerindian population of that island, killing about one-third of them. Smallpox spread to Cuba in 1518 and Puerto Rico in 1519, where over half the native population succumbed to the disease.

In 1519 Cortés and his followers sailed from Cuba to Mexico and arrived in November in Tenochtitlán, whose size and splendour amazed them. Jealous of Cortés' good fortune, the Governor of Cuba sent another expedition under Narváez to replace Cortés. Narváez landed near present-day Vera Cruz in April 1520, and his entourage included an African slave who had smallpox. The result (Plate 5.3B) was described by a Spanish friar, who arrived in Mexico in 1525:

"... at the time that Captain Pánfilo de Narváez landed in this country, there was in one of his ships a negro stricken with smallpox, a disease which had never been seen here. At this time New Spain was extremely full of people, and when the smallpox began to attack the Indians it became so great a pestilence among them throughout the

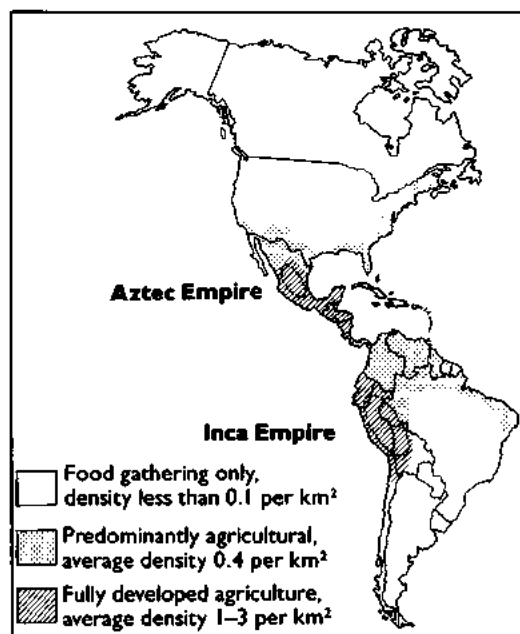

Fig. 5.7. Agricultural development and population densities in the Americas at the time of the European invasions. (Based on McEvedy & Jones, 1978.)

land that in most provinces more than half the population died; in others the proportion was little less. For as the Indians did not know the remedy for the disease and were very much in the habit of bathing frequently, whether well or ill, and continued to do so even when suffering from smallpox, they died in heaps, like bedbugs. Many others died of starvation, because, as they were all taken sick at once, they could not care for each other, nor was there anyone to give them bread or anything else. In many places it happened that everyone in a house died, and, as it was impossible to bury the great number of dead, they pulled down the houses over them in order to check the stench that rose from the dead bodies so that their homes became their tombs. This disease was called by the Indians 'the great leprosy' because the victims were so covered with pustules that they looked like lepers. Even today one can see obvious evidences of it in some individuals who escaped death, for they were left covered with pockmarks." (Foster, 1950.)

From the coast the disease spread inland, reaching the Valley of Mexico in September and shortly after that the capital, Tenochtitlán. The epidemic which followed was catastrophic for the Amerindians and assured the military success of Cortés and his conquistadors. The Aztecs' loss of chiefs and fighting men was serious enough, but the observation

that the Spaniards were immune (from childhood infection in Spain, into which country the Moors had introduced the disease in the 8th century) completed their demoralization. Estimates of the number of deaths vary. Some say that half the population of Mexico died within 6 months; other estimates put the population at 25 million before the conquest and 16.8 million 10 years later. At least half of the Aztecs who caught smallpox died of it. From Mexico, the disease spread south into Guatemala and Yucatán, which may have been ravaged by an earlier outbreak in 1515, and greatly decreased the formerly dense population of the Yucatán Peninsula.

Hearing of the riches of the Inca empire far to the south, the Spaniards decided on further expeditions. Before these could be mounted, smallpox reached the land of the Incas in about 1524–1527, killing some 200 000 of the 6 million inhabitants. Just as important as this widespread devastation, from the point of view of the subsequent Spanish conquest, was the fact that the Inca emperor and his designated heir also died of smallpox, and a disastrous civil war broke out for the succession. These events so weakened the Incas that Pizarro and his small band entered Cuzco in triumph in 1533, to be followed by further epidemics of smallpox.

From then on the history of the Amerindians in the Caribbean islands, Mexico, Central America and Peru is punctuated with epidemics of smallpox that were said to kill "hundreds of thousands"; in 1576, as many as 2 million Mexican Indians were alleged to have died. Colombia and Venezuela were invaded, with the same disastrous consequences for the natives, and Spanish soldiers introduced smallpox into Chile for the first time in 1554, and again in 1561 and 1591. By this time there were many locally born "Spaniards" who had not been exposed to smallpox and some 300 died, as well as countless Indians.

In 1506, by Papal decree, the New World had been divided between the Spanish and the Portuguese. What is now Brazil was the principal Portuguese colony, and it was soon struck by smallpox. The first introduction, in 1555, followed the establishment of a French Huguenot settlement, to be followed by fresh introductions by African slaves in 1560, and from Portugal in 1562 and 1563. The last epidemic spread along the coast and along the rivers into the Indian populations of the forested interior and was said to have killed

more than half the natives of the state of Bahia.

By 1588, epidemics of smallpox erupted over the whole South American continent, and subsequently wave after wave of epidemic smallpox decimated the native populations. The resulting depopulation had as important an influence on the history of South America as the supportive role of smallpox in the conquest of Mexico and Peru. No part of the continent was spared—not even the interior of Brazil, whose inhabitants were exposed through the enthusiasm of Jesuit missionaries for converts. As late as 1660, after the Jesuits had established missions along the banks of some of the great rivers, where some 100 000 Indians had been assembled, a smallpox epidemic killed 44 000 of them, to be followed by another 9 years later, which claimed 20 000 victims.

Variolation was introduced into the colonies in 1728 by missionaries from Portugal, but it was not extensively practised. Smallpox continued almost uncontrolled throughout the 18th century, occurring as an endemic disease with epidemics every few years. The last and best-described epidemic, before vaccination became available, occurred in Mexico in 1797. It was notable in that over 60 000 inoculations with variola virus were performed during the epidemic. While protecting most of those inoculated, the practice may have contributed to the spread of smallpox. The changed nature of the population was evidenced by the fact that three-quarters of the estimated 100 000–150 000 cases were in persons less than 20 years old. The case-fatality rate among 3300 variolated individuals was 3.5%, compared with 18.5% among 58 000 naturally acquired cases of smallpox.

The early years of the 19th century were marked by successful struggles for independence throughout South America. Brazil proclaimed its independence from Portugal in 1822, and in 1824 Spanish rule was ended in Peru, the last Spanish colony. From as early as 1798 attempts were made to introduce Jenner's vaccine, of which the most dramatic was the Balmis-Salvany Expedition of 1803–1806, ordered by King Carlos IV of Spain (Smith, 1974), in which 20 orphans were used for successive arm-to-arm transfer of the vaccine during the voyage. However, smallpox continued in all parts of the continent throughout the 19th century, as an endemic disease punctuated periodically by epidemics, especially in the densely populated port cities.

The most profound demographic effect of European conquest, achieved in large part by smallpox, was on the native populations of the islands of the Caribbean, where the population was virtually wiped out, to be replaced by African slaves and Spanish conquerors and their descendants. On the mainland the size of the Amerindian populations of the Aztec and Inca empires ensured their survival; over half the present populations of Mexico, the countries of Central America, Bolivia, Colombia, Ecuador, Paraguay, Peru and Venezuela are of Amerindian stock; elsewhere in North and South America they constitute a small minority.

### North America

In contrast to the urban civilizations of Mexico and Peru, the vast area of America to the north of Mexico was occupied by an estimated 3 million Amerindians, living as hunter-gatherers, and practising a primitive type of agriculture along the eastern seaboard. It was almost a century after the invasion of the Caribbean, Mexico and South America by the Spanish and Portuguese that the east coast of North America was colonized by settlers from France, Great Britain and the Netherlands. Smallpox followed the settlers, the first epidemic in 1617-1619 killing many of the Indians on the Massachusetts coast, thus clearing a place for the settlers who arrived from Plymouth in 1620.

Further outbreaks of smallpox followed, with devastating effect as they spread inland, for the Indians were without immunity and their way of life was disrupted by the epidemics, which affected persons of all ages. Some colonists, being themselves immune from childhood infection, actively fostered the spread of smallpox among the native North Americans (Stearn & Stearn, 1945). The severity of the disease and its spread were exacerbated by the reaction of the Indians to the disease. Terror-stricken relatives of victims fled, carrying the infection with them.

As Crosby (1976) points out:

"... the British tended to drive the Indians away, rather than ensnaring them as slaves and peons, as the Spaniards did, with the result that many of the most important events of aboriginal history in British America occurred beyond the range of direct observation by literate witnesses... Even so, the surviving records for North America do contain references—brief, vague, but plentiful—to deadly epidemics among the Indians, of which

we shall cite a few of the allegedly worst. During the 1630s and into the next decade, smallpox, the most fatal of all the recurrent Indian killers, whipsawed back and forth through the St Lawrence-Great Lakes region, eliminating half the people of the Huron and Iroquois confederations. In 1738 smallpox destroyed half the Cherokees, and in 1759 nearly half the Catawbas. During the American Revolution it attacked the Piegan tribe and killed half its members. It ravaged the plains tribes shortly before they were taken under United States jurisdiction by the Louisiana Purchase, killing two-thirds of the Omahas and perhaps half the population between the Missouri River and New Mexico. In the 1820s fever devastated the people of the Columbia River area, erasing perhaps four-fifths of them. In 1837 smallpox returned to the plains and destroyed about half of the aborigines there."

Not all the settlers were immune, so that smallpox was not, for them, an unmixed blessing. At this time smallpox was endemic in all the larger European cities, with epidemics occurring at intervals of a decade or so. The towns in North America were still too small to support endemic smallpox, so that epidemics occurred whenever the disease was imported at a sufficiently long interval after the last outbreak for enough susceptible persons to have accumulated within the population. The disease usually arrived by ship at the ports on the eastern seaboard, either with settlers from Great Britain or, later, with slaves from Africa. Boston suffered major epidemics in 1636, 1659, 1666, 1677-1678, 1689-1690 and 1697-1698, and there were outbreaks in New York, Jamestown (Virginia), Charleston (South Carolina), and elsewhere. As well as causing substantial numbers of deaths among the settlers, especially those born in the colonies, it disrupted life in the fledgling cities.

One consequence of the obvious association of smallpox outbreaks with cases on ships was the imposition of quarantine measures on ships with infected persons aboard. This was initiated in Boston in 1647, probably for yellow fever, and was later extended to other parts of the colonies. It proved useful in preventing the importation of smallpox. On land, also, attempts were made at various times from about 1670 onwards to prevent smallpox from spreading from Indians to the colonists, and among the colonists, by local quarantine and isolation. Another consequence of the difference in the endemicity of smallpox in the colonies and in Great Britain

### Smallpox and Educational Institutions

"When a French visitor . . . visited William and Mary College in 1702, he was surprised to find as many as forty students there . . . he learned that wealthy parents who formerly had sent their sons to England now preferred the intellectual crudities of a colonial education to the perils of the English smallpox. The Rev. Hugh Jones, in 1724, observed that more Virginians would have been given an English education 'were they not afraid of the Small-Pox, which most commonly proves fatal to them'." (Boorstin, 1958.)

was that many young colonials, who had been brought up in smallpox-free areas, contracted the disease when they went to Great Britain for further studies, or else refused to take the risk and remained on their side of the Atlantic. Indeed, the risk of contracting smallpox in Great Britain was one of the reasons for founding colleges and universities in the colonies.

In the latter part of the 17th century smallpox and military activity interacted in the wars between Great Britain and France, each with Indian allies, in what was to become Canada. With the growth of populations in the port cities on the Atlantic coast and on the banks of the St Lawrence river during the 18th century, smallpox became more frequent and the outbreaks more intense; for example, an epidemic in Quebec City in 1702-1703 was said to have killed nearly a quarter of the inhabitants (Heagerty, 1928). Severe outbreaks occurred in Boston, New York, Philadelphia, and the State of New Jersey, and at the approach of such epidemics many of the townspeople fled to the country. In both New England and the South, smallpox broke the resistance of the Indians to the white invaders, and as white settlement moved westwards it was accompanied by smallpox, to which the local Indians had no resistance. A few of these 18th century epidemics among the Indians were probably initiated, or at least fostered, by whites. The most notorious record is contained in correspondence between Sir Jeffery Amherst, Commander-in-Chief of the British forces in North America, and Colonel Henry Bouquet in 1763, at the time of the Pontiac rebellion:

AMHERST: "Could it not be contrived to send smallpox among these disaffected tribes of Indians? We must on this occasion use every stratagem in our power to reduce them."

BOUQUET: "I will try to inoculate the— with some blankets that may fall in their hands, and take care not to get the disease myself." (Heagerty, 1928.)

By 1785 smallpox had occurred among the Sioux Indians of the Great Plains and crossed the Rocky Mountains with them, and was reported in Alaska and California. Further south, Catholic missions in New Mexico had been invaded by smallpox much earlier, because of their contacts with New Spain.

Quarantine and isolation measures were strengthened, but often proved inadequate. A new element, variolation, entered the struggle against smallpox in 1721, which changed the situation among the whites but not the Indians. That year saw Boston's worst epidemic of smallpox in the 18th century. The epidemic in 1752 was less disastrous only because variolation was practised on a large scale (see Chapter 6, Table 6.2). In this latter outbreak, 1843 of Boston's 15 684 residents fled to the country; 5545 of the remainder caught smallpox, of whom 539 died; 2124 were inoculated, with 30 deaths, and 5998 persons had already had smallpox when the outbreak began. Only 174 susceptible persons who stayed in the city escaped infection (Blake, 1959). When smallpox broke out again in Boston, in 1792, practically the whole town was inoculated within a few days and only 69 deaths from naturally acquired smallpox occurred in the now much larger population.

Smallpox played a part in the Revolutionary Wars, General Washington being particularly anxious about the dangers of smallpox to the Continental army. Indeed, the long duration of the siege of Boston—from June 1775 to March 1776—is considered to have been due in large degree to the existence of smallpox in the city and Washington's fear of attacking it and exposing his army to the

disease. When the British finally left, on 17 March, Washington ordered "one thousand men who had had the smallpox" to take possession of the city. Further north, smallpox in the Northern army was so severe as to decide the course of the war in that region and thus the continued adherence of what is now Canada to the British Crown. In 1777 Washington ordered the compulsory variolation of all new recruits to his armies, an act which prompted a historian (Thursfield, 1940) to write "... I think it is fair to claim that an intelligent and properly controlled application of the only method then known of defeating the ravages of smallpox, which in the years 1775-76 threatened to ruin the American cause, was a factor of considerable importance in the eventual outcome of the War of Independence".

A few years later Jenner published his discovery of vaccination. This was taken up soon after by Dr Benjamin Waterhouse, the first Professor of Medicine at Harvard University, who received news of Jenner's discovery in 1799 and was immediately excited by it. Despite imperfect vaccine, widespread vaccination of the white population reduced smallpox during the early 19th century, although epidemics still occurred in the cities; between 1800 and 1850 Philadelphia had 8 epidemics, Boston 6 and Baltimore 3. Complacency and a failure to maintain supplies of the virus, as well as lack of recognition of the need for revaccination, contributed to the continued presence of smallpox among the white population, but their suffering paled before that of the Indians. Massive and devastating pandemics which occurred in 1801-1802 and in 1836-1840 led to the virtual extinction of many tribes of indigenous North Americans. The second outbreak affected the Indian population over the whole of the North American continent west of the Mississippi river, from Texas to Alaska and from St Louis to California.

One result of these terrible epidemics was the Federal decision to vaccinate the survivors, so that by the second half of the 19th century the Indians were better vaccinated than the white and black inhabitants of North America, many of whom refused vaccination. In the late 19th century smallpox was more severe in the non-Indian population, among whom there were 3 widespread epidemics, in 1865-1866, 1871-1875, and 1881-1883.

In spite of the adoption of vaccination by the United States army in 1812, this precau-

tion was neglected when regiments were raised for the Civil War in the 1860s. In the Union army, there were 6716 cases of smallpox with 2341 deaths among the Negro troops and 12 236 cases with 4717 deaths among the 431 237 white troops. The disease spread among the Confederate army, as well as among civilians on both sides. Indeed, President Lincoln was probably febrile with the prodrome of smallpox when he gave the Gettysburg address on 19 November 1863; his rash appeared on 21 November.

The slave trade, with its threat of smallpox importations, had been made illegal in the British West Indies in 1807 and in the USA in 1808, but after the Civil War migration from Europe increased greatly, and with it the risk of further importations of smallpox from that continent. Between 1871 and 1873 there were widespread outbreaks in Philadelphia, Baltimore, Washington, Cincinnati, New York, Boston and Chicago. A smaller series of outbreaks occurred in the early 1880s, by which time the railway network helped to spread the disease rapidly throughout the continent.

The closing years of the 19th century were marked by the appearance and spread of variola minor in Canada and the USA, a phenomenon described later in this chapter and in Chapter 8 (see Chapter 8, Fig. 8.4).

## SMALLPOX IN OCEANIA BETWEEN 1789 AND 1900

Oceania is a term used to embrace Australia and the islands of the Western Pacific, including New Zealand and Papua New Guinea.

### Australia

The existence of a "Great South Land", to "balance" the continents of the Northern Hemisphere, had long been suspected, and from the mid-16th century onwards several European explorers had made contact with parts of it. The prelude to European colonization was the first voyage of James Cook in 1768-1771, in which he charted the east coast of Australia. The loss of its American colonies shortly after this led Great Britain to seek some other distant place for the disposal of the victims of its repressive laws, and the new continent looked ideal. The First Fleet, comprising 11 ships carrying about 1500

persons—convicts and their guards and keepers—sailed from England on 6 January 1787, called at Rio de Janeiro on 4 August and at Cape Town on 13 October, and arrived in Botany Bay, just south of the present city of Sydney, on 20 January 1788. No addition was made to the infant colony until the arrival of the Second Fleet in 1790.

The early navigators had already reported that the country was inhabited by primitive dark-skinned people, and recent archaeological studies show that aborigines had been in Australia for at least 40 000 years. The late 18th century was a period of severe smallpox in Great Britain, mitigated somewhat by the increasing adoption of variolation. Knowing that the natives of other distant lands, such as South Africa and the East Indies, were infected with smallpox, the surgeons of the First Fleet brought with them "variola matter in bottles" for inoculation if it proved to be necessary. In fact they found a sparse population of hunter-gatherers who, like the aboriginal Americans, were free of smallpox, measles and most other of the common infectious diseases of Europeans.

However, in 1789, only a year after the landing, an outbreak of what was probably smallpox was recognized among the aborigines near the new European settlement, Sydney town, and appears to have spread far and wide among the aboriginal population of south-eastern Australia, as determined by explorers and by later commentators (Cumpston, 1914; Butlin, 1983, 1985; Campbell, 1983, 1985). None of the white settlers was affected, but one coloured seaman suffered from the disease. The origin of this outbreak has never been determined, but two possibilities have been canvassed. Although there is no record of the variola matter brought by the surgeons of the First Fleet ever having been used, lost or stolen, it was a potential source of infection. On the other hand, the newly arrived Europeans may, by chance, have witnessed the passage through the Sydney area of a very rare epidemic of smallpox that had been introduced along the north coast of the continent and spread southwards.

There was little contact between aborigines and whites, except near Sydney, for many years after this, and smallpox appears to have been absent until 1829–1831, when it spread extensively through the indigenous population of south-eastern Australia, affecting a few Europeans as well. Once again, its origin was never determined. Two other outbreaks

of smallpox occurred among the aborigines in the 1860s, the first extending from the north coast across central Australia to the southern coast between about 1861 and 1866, and the second extending along the north-west coast in 1865–1869 (Fenner, 1985). Both probably originated from the voyages of trepang traders coming from the islands to the north of Australia. Butlin (1983) has recently analysed the demographic effects of the 1789 and 1829 outbreaks and suggests that they played an important role in the great decline of the aboriginal population of south-eastern Australia in the first half of the 19th century.

The subsequent history of smallpox in Australia has been documented in great detail by Cumpston (1914). The first outbreak among Europeans occurred in Melbourne in 1857, originating from a ship hailing from Liverpool, England. There were 4 deaths among the 16 persons affected. Six other outbreaks of smallpox occurred in 3 of the colonies before the end of the 19th century, due to importations by passengers on ships; in addition, there were another 16 episodes in which one or two cases occurred, but their source could not be traced. The largest outbreak during the 19th century took place in 1881–1882 in New South Wales, with 154 recognized cases, occurring over a period of 6 months.

But for strict quarantine regulations there would have been many more outbreaks; Cumpston (1914) lists 145 ships quarantined for smallpox in Australian ports between 1828 and 1900, in which smallpox occurred but did not spread to persons on land. The passengers and crew on these vessels had acquired smallpox in many different ports; Cumpston lists 19 countries, located in every continent, as the sources of smallpox.

### New Zealand

New Zealand was settled by Polynesian seafarers about a thousand years ago and by Europeans in 1840. During that year an immigrant ship arrived with cases of smallpox on board, but quarantine prevented spread to the colonists. No further mention of smallpox occurred until 1872, when 2 ships arrived with smallpox on board and 6 local cases occurred in Auckland. Between then and 1904 several other ships arrived with cases on board, but extension to the colonial popula-

tion occurred only in 1874 and 1903–1904 (Maclean, 1964).

### Papua New Guinea

Smallpox was never endemic in Papua New Guinea, but occasional outbreaks occurred before and shortly after European settlement. Mikloucho-Maclay (1975), the first white man to live in the Astrolabe Bay area, noted pockmarked natives in 1872, and records that "the illness came from the north-west and many died of it".

The German colonists of northern New Guinea (Kaiser Wilhelmsland) recorded outbreaks in June 1893, introduced by a Malay seaman on a German ship, and again in 1895. They obtained vaccine from Batavia and treated "thousands of natives", but reconnaissance a year later showed that they did not entirely prevent the disease:

"The great villages, whose armed men had previously by a show of arms prevented us from entering, now contained only the wretched remnants of their former population. The survivors greeted us with lamentations and showed us the mass graves of those claimed by the epidemic. Thanks to the vaccination program which had been carried out, it did not spread any further northward along the coast. Nor did it advance to any extent inland, as the profound hostility between the coastal and mountain inhabitants cut both parties off from all contact." (Sack & Clark, 1980.)

### Other Pacific Islands

Although measles was brought to Fiji in 1875 and killed about 25% of the indigenous population, smallpox never occurred there, which was surprising in view of the large introductions of labourers and their families from India. Nevertheless, it was the fear of the introduction of smallpox that led in the 1880s to the training of young Fijians as vaccinators, and ultimately to the establishment of the Fiji Medical School.

None of the smaller Pacific islands had a population large enough to support endemic smallpox. However, smallpox is said to have reached the Palau Islands in 1783, and in 1854 an epidemic occurred in the Carolines in which 2000 of the 5000 inhabitants died. A severe epidemic in Guam in 1856 killed some 5000 persons out of the total population of 15 000 (Mumford & Mohr, 1943). In 1853 a ship from San Francisco brought smallpox to

Hawaii for the first time, and the disease killed 8% of the indigenous inhabitants within 8 months. Smallpox was introduced into Easter Island in 1863–1864, when islanders who had been forcibly removed to Peru were returned to their home, following intense international pressure. The combined effects of smallpox and tuberculosis reduced the population of the island to an all-time low of 110 persons.

### THE APPEARANCE AND SPREAD OF VARIOLA MINOR

As mentioned in Chapter 1, the occurrence of a distinctive very mild variety of smallpox was reported by Korté (1904) in South Africa as a disease that had been common there for some years, and it was recognized at about the same time (1896) in the USA (Chapin, 1913). The disease that Korté described as "amaas or kaffir-pox" is clearly identifiable as variola minor. Since it appeared to have been endemic in southern Africa for a few years before it was first described there (Brown, 1896), Chapin & Smith (1932) suggested that the disease first observed in Florida in 1896 may have originated in southern Africa. However, recent investigations of the biological characteristics of the viruses that caused variola minor in Brazil in the 1960s and in Botswana, Ethiopia and Somalia in the 1970s (see Chapter 2) suggest that there may have been at least two separate origins of variola minor viruses—one in North America and one or possibly two in Africa.

The descriptions of variola minor in South Africa are unequivocal (Brown, 1896; Korté, 1904), but it is difficult to visualize how the virus spread from there to countries in eastern and central Africa. Burton (1860) provides a clue to a possible independent origin of variola minor in eastern Africa. In his description of the lake regions of central Africa, he refers to smallpox as "the most dangerous epidemic" in eastern Africa, but goes on to state: "There is a milder form of the malady, called *Shirúá*, resembling the chickenpox of Europe."

From the time of recognition of this disease entity at the end of the 19th century, southern and eastern Africa, the USA and to a lesser extent Europe appear to have been the centres of distribution of variola minor viruses. The appearance and behaviour of variola minor in different countries will be traced in greater

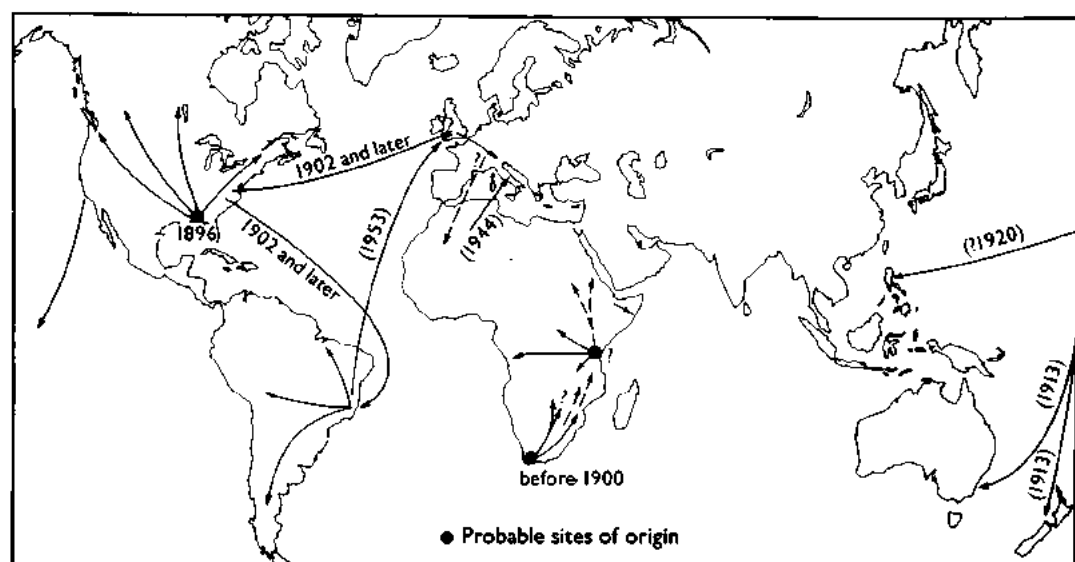

Fig. 5.8. The spread of variola minor from the USA to other parts of the world, and within Africa. Figures in brackets indicate dates of importations that did not result in the establishment of endemic variola minor.

The situation in Africa is complex and the routes of spread are unknown. Variola minor was present in South Africa from the end of the 19th century. It occurred, often together with variola major, in most countries in southern, eastern and central Africa at least from the 1930s onwards. It was probably carried from Europe across the Mediterranean to North Africa (and back to Italy in 1944) and possibly from Great Britain to the British colonies in eastern Africa. There may also have been a third, independent, focus of origin of variola minor somewhere in eastern Africa.

detail in Chapter 8, in which the smallpox situation in selected countries during the first half of the 20th century is described, but although this account covers the period beyond 1900 it is useful to give an overview of the global spread of variola minor here.

In the USA, variola minor rapidly spread all over the country (see Chapter 8, Fig. 8.4), and from there to Canada, Great Britain and South America. Later it was exported from the USA to Australia, New Zealand and the Philippines (Fig. 5.8), although it did not persist in those countries. It was the only form of endemic smallpox in Great Britain between 1920 and 1934, in the USA after 1926, and in Brazil after 1930, and was eventually eliminated from Great Britain in 1934, from the USA in the early 1940s, and from Brazil in 1971.

The spread of variola minor in Africa is much more difficult to trace, because of the lack of reliable records in most countries of that continent. It probably spread from Europe to North Africa in the 1930s, to become endemic in Algeria during the 1940s, whence it spread back to Sicily and Italy in 1944. From the 1930s variola minor occurred contemporaneously with variola major in

Kenya, the Sudan, Tanganyika and Zaire. It was endemic in South Africa and neighbouring countries (present-day Botswana, Lesotho and Swaziland) from early in the 20th century, at first contemporaneously with endemic variola major; then, when this disease was eliminated (see Chapter 20), it became the only endemic form of smallpox, although there were periodic outbreaks of variola major associated with importations from other parts of Africa and from Asia.

Both varieties of smallpox occurred in the Sudan in the 1930s. Early records, reviewed by Pankhurst (1965), show that at least until the 1920s smallpox was a severe disease in Ethiopia, periodically causing outbreaks associated with high case-fatality rates. Variola minor was the only variety of smallpox found there in 1971, when the Intensified Smallpox Eradication Programme commenced operations, but there is no information about when it appeared and variola major disappeared.

#### SUMMARY: SMALLPOX FROM ANTIQUITY TO THE END OF THE 19th CENTURY

The origins of smallpox are unknown and most early references to it are unreliable. The

earliest credible evidence is to be found in the Egyptian mummies of persons who died some 3000 years ago. It is not unreasonable to suggest that it was transferred from Egypt by land or water to India, where it remained as an endemic human disease for some 2000 years and perhaps longer. In the 1st century AD it was introduced into China from the south-west and became established in the local population, and in the 6th century it was carried from China to Japan. In the west, smallpox made periodic incursions into Europe but did not become established there until the population increased and population movement became more active during the time of the Crusades.

As populations grew in India, China and Europe, smallpox became established in the cities and more populous areas as an endemic disease affecting mainly children, with periodic epidemics that killed up to 30% of those infected. Its impact steadily increased, and by the 16th century it was an important cause of morbidity and mortality in Europe, south-western Asia, India and China. The occurrence of the disease in Europe was of special importance, for this served as the focus from which smallpox spread to other parts of the world, as an accompaniment of successive waves of European exploration and colonization.

In 1507 smallpox was introduced into the Caribbean island of Hispaniola and in 1520 into the mainland of the Americas, in Mexico. It struck the native Amerindians with great severity and was an important factor in the

conquest of the Aztecs and the Incas by the Spaniards. Settlement of the east coast of North America occurred about a century later and was also accompanied by devastating outbreaks of smallpox among the Amerindians, and subsequently among the native-born colonists.

By the mid-18th century smallpox was a major endemic disease everywhere in the world except in Australia and in several small islands. It was introduced into Australia in 1789 and again in 1829 and caused devastation among the aborigines, but quickly died out on both occasions.

The widespread use of variolation in a few countries, notably Great Britain and its North American colonies, somewhat mitigated the impact of smallpox among the wealthy classes during the latter part of the 18th century, but a real reduction in its incidence did not occur until vaccination was widely used during the 19th century. Improved vaccines and the practice of revaccination led to a substantial lessening of the ravages of smallpox in Europe and North America, but at the end of the 19th century it remained almost unchecked elsewhere.

Just before the close of the 19th century a much milder form of smallpox, *variola minor*, was recognized in the State of Florida, USA, and in South Africa. From Florida it spread all over the USA and then into Canada, the South American countries and Great Britain. By the mid-20th century *variola minor* occurred along with *variola major*, in varying proportions, in many parts of Africa.

## CHAPTER 6

# EARLY EFFORTS AT CONTROL: VARIOLATION, VACCINATION, AND ISOLATION AND QUARANTINE

### Contents

	Page

Control by isolation and quarantine	273
Quarantine for shipping	274
Isolation of cases	274
The establishment of smallpox hospitals	275

### INTRODUCTION

Besides killing many of those who were infected, an attack of smallpox left most of its survivors pockmarked, and it was realized in ancient times that pockmarked persons never caught smallpox again. By accident, it was found that persons who were infected with smallpox via a scratch on the skin suffered a much less severe form of the disease.

Long ago, in places in which smallpox had become endemic, a connection must have been made between these observations, and attempts to ameliorate the severity of smallpox were initiated by administering the pustular fluid or the dried scabs to persons

who had not had smallpox. The disease which followed such artificial infection was like smallpox, but usually much milder. In some such way, the practice arose of inoculation with smallpox pus or scabs—or "variolation" as it was eventually called, to distinguish it from vaccination. It may have developed independently in China and India, because different routes of inoculation, nasal and cutaneous respectively, were used in these countries. It was said to have been introduced into Egypt by the Mamelukes in the 13th century, and was known in North and western Africa, at least from the late 17th century. It is impossible to know whether it was indigenous in Africa or spread to that

### Clinical Differences between Smallpox after Variolation by the Cutaneous Route and "Natural" Smallpox

Variolation would never have been adopted so widely if it had not caused a less severe disease, and been less likely to kill or cause permanent pockmarks, than naturally acquired smallpox. The difference in mortality varied, but commonly the case-fatality rate was 0.5–2% after variolation, compared with 20–30% after natural smallpox. The symptomatology was also different. A primary lesion appeared at the inoculation site on about the 3rd day (see Chapter 3, Fig. 3.1) and commonly there were satellite pustules around the site of inoculation (see Plate 6.2), but usually a much less severe generalized rash occurred than in ordinary-type smallpox. The reasons for the difference in severity are not known; possible explanations are given in Chapter 3. In any event the virus was not attenuated and one of the major disadvantages of variolation was that it could spread to susceptible contacts to produce severe natural smallpox.

continent along with smallpox itself, possibly with Arab traders who had themselves learned of the practice in India.

Early in the 18th century, variolation spread through the Balkans into central Europe and from Turkey to Great Britain and subsequently to other countries of Europe. It became popular and widely used in some countries, especially in Great Britain and its colonies in America. Then, at the end of the 18th century, Edward Jenner showed by experiment that inoculation with cowpox virus would protect people against smallpox, with very much less constitutional disturbance and danger, to themselves and others, than was the case with variolation. The new procedure rapidly became popular and was adopted all over the world, although in some countries variolation continued to be practised as well for many years.

This chapter traces the discovery, spread and popularization of variolation and subsequently of vaccination, and then outlines the way in which, in parallel with preventive inoculation, concepts of contagion led to the notions of isolation and quarantine. Table 6.1 presents a summary of the important historical events in these fields, from the 10th to the 19th century. Development of the vaccine during the first half of the 20th century is described in Chapter 7 and its use to eliminate smallpox from most of the industrialized countries during that period is outlined in Chapter 8. Chapter 11 describes later developments in vaccine production and vaccination procedures that occurred during the Intensified Smallpox Eradication Programme.

## VARIOLATION

Called smallpox inoculation, insertion, engrafting, or transplantation by 18th century authors—terms derived from the horticultural procedures for inserting a bud into a plant—the practice of cutaneous inoculation of material from smallpox pustules later came to be called "variolation", to distinguish it from the practice of vaccination with material from cowpox lesions, introduced in 1798 by Edward Jenner (Plate 6.4).

### Variolation and Vaccination Performed with Different Viruses

It is important to emphasize that different species of *Orthopoxvirus* were used for variolation and for vaccination. The active agent in variolation was variola virus, the agent that caused smallpox in man, and after a successful cutaneous inoculation there was always a severe local lesion, usually with many satellite pustules (Plates 6.1–6.3), and a generalized rash customarily occurred that was sometimes quite extensive. Severe constitutional symptoms were common and sometimes subjects died of smallpox produced by variolation. Inoculation of variola virus by insufflation (the Chinese method), if successful, also produced a generalized rash and usually more severe symptoms than those produced by cutaneous variolation. Unlike the viruses later used for most other live virus vaccines, the agents used for vaccination

Table 6.1. Important events in the history of smallpox control, from ancient times to 1900

Variolation	Vaccination	Isolation and quarantine
<b>10th century</b>		
Variolation first reported in China, by insufflation, as a secret rite. Probably also practised in India at this time, by cutaneous inoculation.		Hospitals for smallpox established in Japan (ishinho, 982).
<b>13th century</b>		
Variolation by cutaneous route introduced into Egypt by Mamelukes.		
<b>17th century</b>		
Variolation more widely used in China. K'ang Hsi (1661-1722) variolated his soldiers and his children.		Quarantine introduced to control entry of smallpox into North American ports (Boston, New York, Philadelphia; 1650s). Mandatory isolation of smallpox cases at home (Virginia, 1667).
<b>18th century</b>		
Papers on variolation published by Royal Society of London (Chinese method, 1700; Turkish method: Timoni, 1714; Pylarini, 1716). Cotton Mather told of variolation by his African slaves (Boston, 1706). Variolation by cutaneous route carried out in Great Britain (Sloane, 1721), Bohemia (Reiman, 1721) and Boston, USA (Boylston, 1721). Variolation popularized in England by the Suttons (1726). Dimsdale variolates Catherine the Great and variolation accepted in Russia (1768). Louis XV dies of smallpox and variolation accepted in France (1774). Washington orders variolation of the Continental army (1777).	Publication of Jenner's <i>Inquiry</i> (1798).	London Small-Pox and Inoculation Hospital established (1746). Eradication of smallpox by systematic variolation of population and isolation of cases suggested by Haygarth (1793) and Carl (1799).
<b>19th century</b>		
Variolation banned in Russia (1805), Prussia (1835), Great Britain (1840) and British India (1870), but still widely practised in Afghanistan, China and many parts of Africa.	<i>Inquiry</i> translated into several European languages (1800-1802). Vaccination adopted in most European countries and in the USA (1800-1803). Vaccine sent successfully to Bombay (de Carro, 1802) and to South and Central America, the Philippines and Macao (Balmis-Salvany Expedition, 1803-1806). Primary vaccination of infants made compulsory in Bavaria (1807), Denmark (1810), Norway (1811), Bohemia and Russia (1812), Sweden (1816), Hanover (1821) and Great Britain (1853). Revaccination introduced into Württemberg (1829). Vaccination compulsory in Prussian army (1833). Vaccine produced in calves (Italy, 1805, 1810). Vaccine passaged in calves for production (Negri, 1840). Production in calves adopted in France (1864), Belgium (1865), Great Britain (1881) and Germany (1884). Use of glycerol as diluent introduced in Italy (Negri, 1840s). Glycerolated vaccine popularized by Copeman (1892). Jenner's arm-to-arm vaccination banned in Great Britain (1898).	Control of smallpox by isolation of cases and quarantine of contacts ("Leicester method", 1870); reinforced by vaccination of contacts (Millard, 1914).

**Plate 6.I.** Engravings by George Kirtland of coloured drawings made in 1801 by Captain C. Gold, showing the appearance of the local lesions at various times after variolation and vaccination. They were published by Kirtland in 1806 and independently reproduced from the original drawings in the Jenner Centenary Number of the *British medical journal*, published on 23 May 1896. Variolation and vaccination are represented on the 5th and 7th days after inoculation.

### The Art of Variolation in China

"... the art was first taught by a nun in the reign of Jen Tsung (A.D. 1023-63). That reign was signalled by a famous premier, Wang Tan, a great statesman and scholar. Small-pox had deprived him of all his children, and when in old age a son was born to him he was most solicitous to secure for that child a safe attack of the fell disorder... An officer at the capital, a native of Szechwan, hearing of the circumstances, obtained an introduction to the minister and gave him the following information. A young woman of Kiangsu vowed to quit the world, and, rejecting marriage, devoted herself to the worship of Buddha, but refused submission to the tonsure, preferring to retain her hair. She wandered to Omei Mountain (sacred to Sakyamuni, contiguous to Thibet), and on its summit lived in a reed hut. The women of all that region became her disciples, fasting, reciting prayers and doing good. Recently she told her followers that she had been inspired to impart instruction in implanting smallpox, which consisted in selecting scabs from cases that had had but few pustules, and these pointed, round, red and glossy, full of greenish-yellow pus that became thick. The scabs to be used when a month old, or in hot weather those that had fallen only 15 or 20 days might be used, while winter ones should be 40 or 50 days old before using, which may be in spring or autumn. Take 8 grains of the desiccated scabs and 2 grains of *Uvularia grandiflora*; pound the two together in a clean earthen mortar. Select lucky and eschew unlucky days for implanting. Employ for the operation a silver tube curved at the point; blow the prepared matter into the right nostril in the case of a boy, and into the left in girls; six days after there is slight fever, which on the following day increases greatly; in two or three days more an eruption appears, charged with matter, and then scabs. Not one in 10, not one in 100, that does not recover. All the inhabitants of the region adjacent to Omei Mountain adopted the practice, praying her to perform the operation. On hearing this the minister sent for the venerable recluse, who came to the capital and operated successfully... She returned to the sacred mountain, and some years later informed her followers that she was not uterine born, but was an incarnation of the Goddess of Mercy, and had come to preserve the lives of children by implanting small-pox, 'which,' said she, 'I have taught you, that you should impart the art to others.' On hearing this announcement the women all worshipped her, lauding her righteousness, asking by what title they should invoke her. She answered, 'As Your Ladyship the Celestial Mother,' adding 'whenever anyone shall offer incense and prayers to me, invoking my intervention, I will from heaven manifest myself by turning malignant into benignant cases'; whereon she was transformed, that is, she died. Every official temple has a shrine to this 'Goddess of Smallpox' and many cities have temples for her exclusive worship. Evidently inoculation had been taught at Omei Mountain by some Thibetan monk, who had acquired his art in India, where it appears to have been known in high antiquity." (Macgowan, 1884.)

against smallpox were not attenuated strains of the virus that caused smallpox (variola virus), but a totally different species of *Orthopoxvirus*, initially cowpox virus and subsequently vaccinia virus. Both these viruses produced a localized lesion at the site of cutaneous inoculation, without satellite or generalized lesions except in very rare cases, and they were only very rarely transmissible to other persons. Neither cowpox nor vaccinia virus can be "transformed" into variola virus, nor is the reverse possible (see Chapter 2); both provided a high degree of protection against smallpox, for at least several years.

### Variolation in China

The early practice of variolation is better documented in Chinese literature (Needham, 1980) than in Indian. It appears to have begun as a secret procedure about AD 1000, and did not become public knowledge until about AD 1500, when writings about it appeared in Chinese medical books. The mode of inoculation was by the intranasal insufflation of powdered scab material (see Plate 6.14B). Descriptions of the method of preparing the inoculum show a realization that its activity persisted for longer in winter than in summer

### Method of Variolation in India

"The operation of inoculation called by the natives *tikah* has been known in the kingdom of Bengall as near as I can learn, about 150 years . . . Their method of performing this operation is by taking a little pus (when the small-pox are come to maturity and are of a good kind) and dipping these in the point of a pretty large sharp needle. Therewith [they] make severall punctures in the hollow under the deltoid muscle and sometimes in the forehead, after which they cover the part with a little paste made of boiled rice." (Coult, 1731.)

and that it was sensitive to sunlight and excessive heat. Fresh scab material was supposed to be stored "on the person" (i.e., at about 37 °C) for up to a month, a prescription that ensured that it contained little active virus, but consisted in large part of inactivated virus. Intranasal insufflation was still employed as a method of variolation in some parts of China in the 20th century (Tao, 1935). Cutaneous inoculation with variola virus appears not to have been practised there until after vaccination by the same route had been introduced in 1805 (Jiang Yutu, personal communication, 1982). Surprisingly, the Japanese were ignorant of variolation until about the mid-18th century, when the practice was introduced from China.

### Variolation in India and South-western Asia

Hopkins (1983a) suggests that variolation had been practised in India for centuries, an opinion with which we agree, although there is no documented evidence of its use before Europeans settled there in the 16th century. From then onwards there are several references to inoculation against smallpox, usually by the cutaneous route, in the writings of European visitors. Variolation was made illegal in British India in 1870, but it continued to be practised on a reduced scale, particularly in the princely states, until recent times. It was common in Afghanistan and parts of Pakistan up to the 1970s, occasionally accompanied by a high case-fatality rate (see Chapter 14).

From India the practice spread to various countries in south-western Asia and thence into central Europe via the Balkans, and probably with Arab slave traders to eastern and western Africa. However, nowhere in Asia was variolation used as a systematic

large-scale effort to prevent smallpox, in the way it was developed by some of its practitioners in Great Britain during the latter part of the 18th century.

Detailed European knowledge of variolation came via two routes: through the Balkans to central Europe, where it was extensively practised in Slovakia very early in the 18th century (Dubay, 1972), and from the Turks in Constantinople, where it is said to have been introduced during the 17th century, probably from India. The Ottoman Empire was then a powerful independent state, the nearest place to Europe in which the "exotic practices" of the Orient could be seen at close hand, and a succession of descriptions of the procedure of inoculation were made by European visitors to Turkey.

### Introduction of Variolation into Europe

In contrast to the paucity of published information on variolation elsewhere, there is a large literature on its introduction and spread in Europe (Miller, 1957) and North America. Variolation was important in Europe not only because it was practised on a scale that far exceeded that attained elsewhere, and probably influenced the incidence of smallpox in some European countries (Razzell, 1977b), but also because it set the stage for Jenner's discovery of vaccination and its rapid acceptance. Of all the European countries, Great Britain was the most important, as far as variolation was concerned, and the Royal Society of London played a critical role as the focus for reports on the practice elsewhere in the world.

There were apparently folk practices in several parts of Europe in the latter part of the 17th century of "buying the smallpox", which involved sending children to homes in which a patient was recovering from smallpox to buy

WELLCOME INSTITUTE LIBRARY, LONDON

**Plate 6.5.** Lady Mary Wortley Montagu (1689–1742). Suffered from smallpox in 1715 and was left severely pockmarked. Learned of variolation in Constantinople. Her daughter was the first person to be professionally inoculated in Great Britain, in 1721.

some crusts for a penny or two. Also, children were sometimes deliberately exposed to mild cases, or “bedded” with other children who had mild smallpox, so that they might get the disease in favourable circumstances (Miller, 1957).

But, as Samuel Johnson remarked, during the 18th century there was a great passion for innovation, and for innovation from lands foreign to European traditions and knowledge. Thus in the year 1700 two independent reports were made to the Royal Society of London describing the Chinese method of variolation by intranasal insufflation. Then in 1714 and 1716 accounts of the Turkish method of cutaneous inoculation were independently communicated to the Royal Society by the physicians Emanuele Timoni and Jacob Pylarini. However, British doctors were too conservative to follow up these suggestions immediately, in spite of the severity of smallpox at that time.

Lady Mary Wortley Montagu (Plate 6.5) is widely credited with having introduced variolation into Great Britain in 1721, as the funeral monument erected in 1789 in Lichfield Cathedral, 27 years after her death in 1762, attests:

“Sacred to the memory of the right honourable Lady Mary Wortley Montagu, who happily

introduced, from Turkey, into this country, the salutary art of inoculating the small pox. Convinced of its efficacy, she first tried it with success on her own children, and then recommended the practice of it to her fellow-citizens. Thus, by her advice, we have softened the virulence, and escaped the danger of this malignant disease.”

Miller (1981) suggests that this is too simple an explanation, and argues that the introduction of variolation into Western medicine is a classic example of how innovation in medical practice occurs. The process includes the urgent need for a method of prevention or cure, a promising solution, a strongly supported programme of experimentation and study and prominent examples of the effectiveness of the new procedure if it is to gain acceptance. With inoculation against smallpox, the first component was obvious and the second provided by the succession of reports and discussions at the Royal Society of London on inoculation as practised in China and Turkey. The major force in study and experimentation was Sir Hans Sloane, who was the king's physician and President of the Royal Society. Through his influence, when the time was ripe, royal sanction was given to experiments on prisoners, and then prominent examples of its use were provided when in April 1722 two royal princesses, Amelia and Caroline, were inoculated, under Sloane's supervision. By the end of the century, Woodville (1796), in his comprehensive history of variolation, extolled Lady Mary's virtues and concluded: “It is therefore highly probable, had it not been for the uncommon fortitude of Lady Mary Wortley Montague... that the era of the commencement of inoculation in this country would have been much later than here stated.” Miller attributes the credit given to Lady Mary Wortley Montagu to her vivacity and prominence in British society, her considerable skill with the pen, the common knowledge that her daughter was the first person in Great Britain to be inoculated, and the advertisement of her activities, especially by Voltaire.

In the same year as this highly publicized operation, Dr Johann Adam Reiman carried out smallpox inoculations in Bohemia, following earlier articles (see, for example, Reiman, 1721) discussing the rationale of the practice. The 250th anniversary of Reiman's performance of the first variolation in continental Europe was celebrated by a scientific

conference in Prešov, Czechoslovakia, in 1972 (Dubay, 1972). Clearly, smallpox was then so severe in Europe, and contacts with the East were sufficiently numerous, that the time was ripe for the introduction of the only palliative measure known.

The practice spread in Great Britain, although not without opposition, which was based partly on theological grounds and partly on its association with some mortality and with the spread of smallpox to uninoculated contacts. But it was clear from early statistical studies by Jurin (1722) that there was much less of a risk of dying from inoculated smallpox than from naturally acquired smallpox. James Jurin, who was then Secretary of the Royal Society, requested information from inoculators about details of all their inoculations, including a complete description of any fatal cases. The response was excellent, and the Royal Society files contain numerous letters from inoculators and from laymen interested in the practice (Miller, 1981). Jurin produced a series of annual reports between 1723 and 1727 which demonstrated that variolation conferred immunity, since by 1727 there would have been ample opportunity for inoculated subjects to have acquired the natural infection. The death rate for natural smallpox remained constant, at 1 death in every 6 cases; the death rate for inoculated smallpox varied from 1 in 48 to 1 in 60 cases.

Thus, beginning in the 1720s, variolation became an acceptable medical practice in Great Britain, for a combination of reasons that did not operate at the time in other countries of Europe. Opposition was particularly strong in France (Miller, 1957), until it was overcome by the mathematician and geographer, Charles de La Condamine, who began a campaign in 1754 by suggesting that nearly a million deaths could have been averted in France if the country had followed the British precedent in 1722.

The further history of variolation in Europe, especially in France and Great Britain, is developed at length in books by Miller (1957) and Razzell (1977b). The practice having once been accepted by the medical profession of the day, the practitioners of inoculation developed elaborate and expensive regimens to "prepare" children for inoculation and treat them during the ensuing illness, and the incision for inoculation itself became much deeper than previously. Its popularity waxed and waned, depending on a variety of factors: the severity of smallpox at the time, the occurrence of cases and especially deaths among members of Europe's royal families, and encouragement from across the Atlantic. In 1746 the London Small-Pox and Inoculation Hospital was established, and together with the Foundling Hospital it offered variolation free. Further advances occurred in Great Britain in the

### "Preparation" for Variolation

In contrast to the way variolation was performed in Turkey, members of the medical profession in Europe made a deep incision, and, influenced by a belief in the humoral pathology of smallpox, prescribed an elaborate procedure of preparation before carrying out the operation. This was designed to "weaken" constitutions that were too "high", a condition thought to occur in robust and active individuals and accentuated by meat-eating. Preparation therefore took the form of purging, bleeding and restriction to a light diet, which were the measures then used by the medical profession for the treatment of natural smallpox. For example, the regimen was said to include emetics, purgatives and sometimes bleeding, and an abstention from animal food and strong liquors. The period of preparation was lengthened, and for Edward Jenner, when he was variolated as a boy in 1756, the preparation lasted 6 weeks. "He was bled, to ascertain whether his blood was fine; was purged repeatedly till he became emaciated and feeble; was kept on a very low diet, small in quantity, and dosed with a diet-drink to sweeten the blood." Subsequently the procedure was simplified, but not greatly shortened until the late 1760s, when the Suttons' advocacy of a short preparation and a shallow incision popularized variolation in Great Britain. (Based on Razzell, 1977b.)

1760s, when Robert Sutton perfected a much simpler technique of inoculation and, with his six sons, practised it on a large scale. The Suttonian method was in many ways a return to the practice in Constantinople, where the British had learned of variolation: a short period of preparation, or none at all in the face of an epidemic of smallpox, a shallow incision, fresh pustule fluid and no dressing. However, Thomas Dimsdale (1781) criticized the Suttons for allowing their patients to move freely in the community, a practice which produced many cases of smallpox among uninoculated contacts.

The simplified Suttonian method commended itself to physicians elsewhere in Europe, but not before an unprecedented number of royal personages had contracted smallpox, with devastating political effects when one death followed another (Hopkins, 1983a). Other notable events included the inoculation of the Tsarina of Russia, Catherine II, in 1768, by Dimsdale and, eventually, the acceptance of variolation by the French, which was precipitated by the quite unexpected death of Louis XV from smallpox on 19 May 1774.

In Great Britain, variolation by the Suttonian method was practised on a wide scale (Razzell, 1977b), but tended to be neglected in the large towns and cities, in which the risk of dying of smallpox actually increased towards the end of the 18th century.

As well as advocating the Suttonian method, Dimsdale (1767, 1781) recommended measures to prevent spread from inoculated subjects, including "general inoculation" of all the inhabitants of a village at one time, with isolation of those not well enough to be inoculated, since "more lives are now lost in London than before inoculation commenced and the community at large sustains a greater loss". Eventually, in 1793, John Haygarth (Plate 6.6) published "a sketch of a plan to exterminate the casual small-pox from Great Britain" (Haygarth, 1785, 1793; Downie, 1965b) which included "systematic inoculation throughout the country, isolation of patients, decontamination of potentially contaminated fomites, supervised inspectors responsible for specific districts, rewards for observance of rules for isolation by poor persons, fines for transgression of those rules, inspection of vessels at ports, and prayers every Sunday" (Hopkins, 1983a). Carl (1799), then Director of the Inoculation Institute in Brno (Bohemia), made a similar proposal.

WELLCOME INSTITUTE LIBRARY, LONDON

**Plate 6.6.** John Haygarth (1740–1827). Published excellent disease statistics for the city of Chester and developed a plan for the extermination of smallpox from Great Britain by general variolation and the isolation of cases.

The way was prepared for Edward Jenner, who had himself been inoculated as a boy and had practised variolation as a physician, to substitute cowpox virus for variola virus and thus do away with variolation—a development that would ultimately vanquish smallpox forever.

### Introduction of Variolation into the Americas

Roman Catholic missionaries from Portugal introduced variolation into Brazil in 1728, but it was not much used there. Spain had been very slow to accept variolation, and it was not introduced into the colonies of New Spain until the latter part of the 18th century: Chile in 1765, Venezuela in 1769, Argentina in 1777, Peru in 1778, Mexico in 1779 and Guatemala in 1780.

The situation was very different in the British colonies in North America. Stimulated by the occurrence of a severe epidemic of smallpox in Boston in 1721, the Reverend Cotton Mather (Plate 6.7) persuaded a local physician, Dr Zabdiel Boylston, to try variolation as a method of controlling the disease (Blake, 1959). Mather had first learned of the practice from his African slaves in 1706 and had subsequently read the articles

Table 6.2. The use of variolation for the control of natural smallpox in Boston<sup>a,b</sup>

Year	Population	Had smallpox before	Presumed susceptible	Natural smallpox		Inoculation smallpox		Percentage of smallpox cases due to variolation	Left town	Escaped disease

<sup>a</sup> Based on Blake (1953).<sup>b</sup> .. = data not recorded.<sup>c</sup> Most of these were out of town during the epidemic.<sup>d</sup> Including 1038 non-residents inoculated in Boston.

by Timoni and Pylarini in the *Philosophical Transactions of the Royal Society of London*. Variolation at first provoked a violent controversy, but the results of its limited use in the Boston epidemic—6 deaths among 244 inoculated persons (2.5%), compared with 844 deaths among 5980 people who had contracted “natural” smallpox (14.1%)—led to its wider adoption in the colonies, especially in Philadelphia. Nevertheless, there was continued concern about the risk of inoculated persons spreading smallpox; this made the citizens of the colony receptive to Jenner’s proposal to use cowpox vaccine,

which did not carry this danger. However, even before the era of vaccination, Boston and other towns in Massachusetts achieved a measure of control of smallpox (Table 6.2) by combining widespread variolation under careful supervision, including inoculation of the poor, with strict policies of quarantine and isolation.

So great was the disruption of his military plans by smallpox that George Washington, after considerable hesitation, ordered the compulsory variolation of new recruits to the Continental army early in 1777.

### Variolation in Africa

The earliest reference to the existence of variolation in Africa was the discussion between Cotton Mather and his slaves in 1706, which indicated that cutaneous inoculation was a common practice before that time in some parts of western Africa. Later references from European travellers, traders and explorers, summarized by Herbert (1975), show that variolation was widespread in Africa throughout the 19th century. Smallpox was introduced into central Africa late in its history, probably during the early years of the 19th century (see Chapter 5); variolation appears to have been introduced soon afterwards, probably via Arab-led caravans. It was rarely practised on a scale that had an appreciable influence on the overall incidence of smallpox. In some places variolation of all those who had not yet had the disease was carried out when the first cases of smallpox occurred in a village, using material from these cases. Elsewhere—in Ethiopia, for example—the head of a house

NATIONAL LIBRARY OF MEDICINE, BETHESDA

**Plate 6.7.** Reverend Cotton Mather (1663–1728). Had learned about variolation from his African slaves in 1706 and arranged for Dr Zabdiel Boylston to carry out the first variolations in North America in 1721. Portrait by Peter Pelham.

would obtain material when there were reports of cases in the vicinity and variolate the members of his extended family.

The site of inoculation varied from place to place—for example: the forehead, the arm, the leg and the “anatomist’s snuff-box” (on the dorsum of the hand at the base of the metacarpal of the thumb) in different parts of Africa; the forearm and the anatomist’s snuff-box in Afghanistan and Persia. At the turn of the century the French authorities were concerned about the growing popularity of variolation (in preference to vaccination) in Algeria, and it was suggested that the practice “ought to be sternly suppressed in all French colonies” (*Lancet*, 1901). However, variolation continued to be practised up to modern times and was encountered during the eradication programmes in western, eastern and southern Africa (see Chapters 17, 19, 20 and 21).

## THE DISCOVERY OF VACCINATION

The second half of the 18th century saw smallpox at its most destructive stage in Europe, and by this time the practice of variolation was well established as a preventive measure, although it was recognized that occasionally inoculated subjects died and perhaps more often they conveyed severe disease (“natural” smallpox) to their susceptible contacts. There was also the observation among country folk in several parts of Europe that milkmaids were rarely pockmarked, and the local belief was that they were protected because of an infection acquired from cows. As Jenner testified to the House of Commons in 1802, the “vague opinion” of the protective value of cowpox had arisen quite recently among farmers and was probably connected with the observation of the insusceptibility of milkmaids to variolation, practised much more widely during the late 18th century because of Sutton’s improved method.

A few educated men took up this story and when they found a case of cowpox they inoculated material from it into their children. After Edward Jenner had demonstrated by challenge inoculation with variola virus that subjects inoculated previously with cowpox were indeed resistant to smallpox, claims for priority were made by several of

these people: Fewster in 1765, Bose in 1769, Jesty in 1774, Nash in 1781 and Platt and Jensen in 1791 (Dixon, 1962; Baxby, 1981). However, without denying that each of these claimants may have made an inoculation with cowpox to protect against smallpox, the principal credit must go to Edward Jenner, who demonstrated its protective effect by subsequent challenge inoculation with smallpox virus, published his results (Jenner, 1798), and for the rest of his life actively promoted the cause of vaccine inoculation (Baron, 1838; LeFanu, 1951). Subsequently, to honour Jenner, Pasteur (1881) generalized the use of the term “vaccination” to include preventive inoculation with all kinds of infectious agents.

## Jenner’s Observations and Experiments

We cannot do better than Jenner himself in summarizing how he came to carry out the famous experiments on James Phipps on 14 May 1796 (Plate 6.8; Jenner, 1801).

“My inquiry into the nature of the Cow Pox commenced upwards of twenty-five years ago. My attention to this singular disease was first excited by observing, that among those whom in the country I was frequently called upon to inoculate, many resisted every effort to give them the Small Pox. These patients I found had undergone a disease they called the Cow Pox, contracted by milking Cows affected with a peculiar eruption on their teats. On inquiry, it appeared that it had been known among the dairies from time immemorial, and that a vague opinion prevailed that it was a preventive of the Small Pox. This opinion I found was, comparatively, new among them; for all the older farmers declared they had no such idea in their early days—a circumstance that seemed easily to be accounted for, from my knowing that the common people were very rarely inoculated for the Small Pox, till that practice was rendered general by the improved method introduced by the Suttons: so that the working people in the dairies were seldom put to the test of the preventive powers of the Cow Pox.

“In the course of the investigation of this subject, which, like all others of a complex and intricate nature, presented many difficulties, I found that some of those *who seemed to have undergone the Cow Pox*, nevertheless, on inoculation with the Small Pox, felt its influence just the same as if no disease had been communicated to them by the Cow. This occurrence led me to inquire among the medical practitioners in the country around me,

it now becomes too manifest to admit of contro-  
versy, that the annihilation of the Small Pox, the most dreadful  
scourge of the human species, must be the final result of this  
practice.

**Plate 6.8.** Jenner's forecast of smallpox eradication. The full text of this paper is reproduced in this chapter.

who all agreed in this sentiment, that the Cow Pox was not to be relied upon as a certain preventive of the Small Pox. This for a while damped, but did not extinguish, my ardour; for as I proceeded, I had the satisfaction to learn that the Cow was subject to some varieties of spontaneous eruptions upon her teats; that they were all capable of communicating sores to the hands of the milkers; and that whatever sore was derived from the animal, was called in the dairy the Cow Pox. Thus I surmounted a great obstacle, and, in consequence, was led to form a distinction between these diseases, one of which only I have denominated the *true*, the others the *spurious*, Cow Pox, as they possess no specific power over the constitution. This impediment to my progress was not long removed, before another, of far greater magnitude in its appearances, started up. There were not wanting instances to prove that, when the true Cow Pox broke out among the cattle at a dairy, a person who had milked an infected animal, and had thereby apparently gone through the disease in common with others, was liable to receive the Small Pox afterwards. This, like the former obstacle, gave a painful check to my fond and aspiring hopes: but reflecting that the operations of Nature are generally uniform, and that it was not probable the human constitution (having undergone the Cow Pox) should in some instances be perfectly shielded from the Small Pox, and in many others remain unprotected, I resumed my labours with redoubled ardour. The result was fortunate; for I now discovered that the Virus of Cow Pox was liable to undergo progressive changes, from the same causes precisely as that of Small Pox; and that when it was applied to the

human skin in its degenerated state, it would produce the ulcerative effects in as great a degree as when it was not decomposed, and sometimes far greater; but having lost its *specific properties*, it was incapable of producing that change upon the human frame which is requisite to render it unsusceptible of the variolous contagion...

"During the investigation of the casual Cow Pox, I was struck with the idea that it might be practicable to propagate the disease by inoculation, after the manner of the Small Pox, first from the Cow, and finally from one human being to another. I anxiously waited some time for an opportunity of putting this theory to the test. At length the period arrived. The first experiment was made upon a lad of the name of Phipps, in whose arm a little Vaccine Virus was inserted, taken from the hand of a young woman who had been accidentally infected by a cow [Sarah Nelmes; Plate 6.9]. Notwithstanding the resemblance which the pustule, thus excited on the boy's arm, bore to variolous inoculation, yet as the indisposition attending it was barely perceptible, I could scarcely persuade myself the patient was secure from the Small Pox. However, on his being inoculated some months afterwards, it proved that he was secure.\* This case inspired me with confidence; and as soon as I could again furnish myself with Virus from the Cow, I made an arrangement for a series of inoculations. A number of children were inoculated in succession, one

\* \* This boy was inoculated nearly at the expiration of five years afterwards with variolous matter, but no other effect was produced beyond a local inflammation around the punctured part of the arm."

WELLCOME INSTITUTE LIBRARY, LONDON

**Plate 6.9.** Accidental cowpox lesions on the hand of Sarah Nelmes (case XVI in Jenner's *Inquiry*) from which material was taken for the vaccination of James Phipps in 1796.

from the other; and after several months had elapsed, they were exposed to the infection of the Small Pox; some by Inoculation, others by variolous effluvia, and some in both ways; but they all resisted it. The result of these trials gradually led me into a wider field of experiment, which I went over not only with great attention, but with painful solicitude. This became universally known through a Treatise published in June 1798. The result of my further experience was also brought forward in subsequent publications in the two succeeding years, 1799 and 1800. The distrust and scepticism which naturally arose in the minds of medical men, on my first announcing so unexpected a discovery, has now nearly disappeared. Many hundreds of them, from actual experience, have given their attestations that the inoculated Cow Pox proves a perfect security against the Small Pox; and I shall probably be within compass if I say, thousands are ready to follow their example; for the scope that this inoculation has now taken is immense. An hundred thousand persons, upon the smallest computation, have been inoculated in these realms. The numbers who have partaken of its benefits throughout Europe and others parts of the Globe are incalculable: and it now becomes too manifest to admit of controversy, that the annihilation of the Small Pox, the most dreadful scourge of the human species, must be the final result of this practice."

Jenner's home in Berkeley, Gloucestershire (Plate 6.10), has been purchased by the Jenner Trust. It has been developed as a museum which commemorates not only Jenner but also the application of his discovery to the global eradication of smallpox, achieved 181 years after his experiments on Phipps.

### The World-wide Acceptance of Vaccination

At the beginning of the 19th century the educated public was receptive to Jenner's idea. Unlike many other diseases that were common at the time, smallpox struck at all levels of society and was the object of much dread. Variolation had by then been widely accepted; Jenner's vaccine was a way of providing the advantages of variolation without the risks either to the person inoculated or to his fellows (Miller, 1957). And there was no doubt that cowpox produced a much less severe disease than did variolation (Plates 6.1–6.3).

Vaccination was taken up with remarkable speed all over Europe and in the newly independent United States of America. It was, wrote Edward Edwards (1902), "as if an Angel's trumpet had sounded over the earth".

**Plate 6.10.** The Jenner Museum. Edward Jenner bought The Chantry in Berkeley, Gloucestershire, in 1785 and lived in it until he died in 1823. The original cottage dates from 1384 at the latest. Purchased by the Jenner Trust in 1983, the building has been completely restored. The museum was opened on 10 May 1985 and commemorates Jenner, the development of the science of immunology, and the eradication of smallpox.

### Effects of Introduction of Vaccination on Life Expectancy

Vaccination was the only public health measure of any importance that was newly and widely applied during the first quarter of the 19th century. It was enthusiastically accepted in France, where Napoleon gave it strong support, and in Sweden (see Fig. 6.1), two countries for which there were reasonably good vital statistics at that time.

During the early 19th century there was a vigorous controversy as to whether the human life span was fixed (a view supported by Thomas Malthus) or could be extended by public health measures, as the statistician Duvillard maintained (Westergaard, 1932). Data for life expectancy at birth before and after the introduction of vaccination supported Duvillard's view and illustrate what must be primarily the effect of vaccination on life expectancy.

<sup>a</sup> From Hishinuma (1976), rounded to nearest whole number.

Within 3 years of its publication in London, Jenner's *Inquiry* had been translated into German, French, Dutch, Italian and Latin (LeFanu, 1951). Jennerian vaccination was adopted much more rapidly and widely in Europe than variolation had been, and quickly spread around the world, gradually supplanting variolation where that had been practised. In London it was taken up immediately by William Woodville, Director of the London Small-Pox and Inoculation Hospital, and his colleague George Pearson, who in 1799 sent the vaccine, dried on threads, to some 200 physicians in England and to physicians in Paris, Berlin, Vienna, Geneva, Hanover, Portugal and North America. By 1800 vaccination was being practised in Constantinople, Paris and North America, and by 1801 in Moscow and Berlin; by 1802 viable vaccine had been shipped from Vienna to Bombay (Bowers, 1981). Additional challenge inoculations with smallpox, carried out in many places, confirmed Jenner's hypothesis that inoculation with cowpox virus provided protection against smallpox. In Boston, Benjamin Waterhouse (Plate 6.11) demonstrated protection in 7 persons in July 1800 (Blake, 1957) and in 1803, out of 17 000 vaccinations done in Germany, over 8000 had been tested by subsequent variolation (Dixon, 1962). In

the USA, Waterhouse interested the then Vice-President, Thomas Jefferson, in the potential value of vaccination, and Jefferson immediately responded and enlisted the in-

### Early Methods of Distributing Vaccine

From the earliest days of the development of vaccination it was clear that the most certain way of assuring that the vaccine was potent was to take material directly from a pustule—hence the importance of Jenner's demonstration that vaccine could be maintained by the arm-to-arm vaccination of children. The most famous exploitation of this procedure for the long-distance carriage of vaccine was the Balmis-Salvany Expedition, in which 20 orphans were carried on the ship to provide a succession of susceptible subjects for vaccination. However, more convenient methods were clearly needed.

Initially the commonest method was to impregnate threads with vaccine, much as thread impregnated with material from smallpox pustules had been used for variolation. Many of the early shipments between countries were made with such material. Another method was to spread the lymph on a glass slide and, when it was perfectly dry, cover it with a thin coat of mucilage of gum arabic (Paytherus, 1801). Silver or ivory lancets or points were also used, on which vaccine was allowed to dry; sometimes the liquid lymph on the ivory point was enclosed within a wax ball (Baron, 1838). In Great Britain the National Vaccine Establishment took over the responsibility for maintaining serial arm-to-arm transfers in 1808, and distributed several thousand preparations to physicians each year on ivory points or glass slides. Later, capillary tubes filled with glycerolated vaccine were used, but ivory points were still being employed in Great Britain as late as 1898.

With most species of virus all methods of transport except by direct transfer from pustule to arm would have been unsuccessful. However, the poxviruses are relatively so resistant to inactivation that these air-dried or wet preparations, maintained without refrigeration, often contained enough viable virus to produce a pustule in the vaccinated person. Nevertheless, failures did occur in the long-distance shipment of vaccine, as in Jenner's attempts to send material to India via the Cape, in several of the shipments from Great Britain to North America and in many shipments from Batavia to Japan.

terest of laymen and the medical profession in Virginia, Washington, Philadelphia and other places. In December 1801 he arranged for the vaccination of members of an American Indian delegation, supplying them with vaccine and with instructions from Waterhouse about its use (Halsey, 1936).

Perhaps the most dramatic demonstration of the readiness of the world for vaccination was the Balmis-Salvany Expedition commissioned by King Charles IV of Spain, which in 1803–1805 carried vaccine by the arm-to-arm vaccination of orphan children from Spain to the Spanish colonies in the New World, China and the Philippines (Fernández del Castillo, 1960; Smith, 1974; Bowers, 1981).

### Early Problems with Vaccination

In spite of this remarkable record of acceptance, a variety of problems arose. Some of these were due to contamination of the cowpox material, some to shortage of material owing to the absence of infected cows and failure to maintain the virus in human subjects, some to theological and philosophi-

cal objections and some to Jenner's insistence that primary vaccination gave complete and lifelong protection against smallpox.

#### *Contamination of cowpox material with variola virus*

The first evidence of this kind of contamination came very early, from Woodville and Pearson, who had embarked on vaccination at the London Small-Pox and Inoculation Hospital. In January 1799 cowpox was discovered at a dairy at Gray's Inn Lane, and Woodville collected lymph from lesions on one of the milkmaids. With this he vaccinated cases at the Small-Pox and Inoculation Hospital and about two-thirds of some 500 subjects had a generalized eruption. Subsequently Woodville (1800) realized that this was due to cross-infection or contamination with material from smallpox cases, and noted that a generalized eruption did not occur when persons were vaccinated in private houses. Material from some of the hospital patients was widely distributed by Pearson (Baxby, 1981), and Razzell (1977a) has suggested that it consisted of attenuated strains of

variola virus which constituted the source of vaccinia virus. This hypothesis is not supported by biological evidence (see Chapter 2), but the origin of vaccinia virus, the agent used for smallpox vaccine throughout the latter part of the 20th century, is still uncertain (Baxby, 1981).

Viral contamination has been a recurrent, usually unrecognized, problem. During the latter part of the 19th century it was often decided that vaccine produced by repeated arm-to-arm transfer or maintained in cows needed to be enhanced in potency. As well as "humanized lymph" being passed from man back to the cow ("retrovaccination"), cows were inoculated with variola virus from cases of smallpox. Many of the best-known strains of vaccinia virus were purported to have been derived from smallpox cases in this way (see Copeman (1899) and Chapter 11). However, the environment of vaccine lymph institutes was heavily contaminated with vaccinia virus, as Kelsch et al. (1909) showed, when cows in such an institute which had been inoculated in the scarified skin with glycerol on its own developed a few vaccinal vesicles a few days later. Carefully performed experiments in modern times have failed to "transform" variola to vaccinia virus (Nelson, 1943;

Herrlich et al., 1963; Dumbell & Bedson, 1966).

#### *Contamination of human lymph*

With the separation of vaccine maintenance and preparation from the smallpox hospitals, the problem of contamination with variola virus was overcome, but other kinds of contamination posed problems. While arm-to-arm vaccination provided a simple means of maintaining a source of virus, it introduced the possibility of the transfer of other human diseases, especially erysipelas and syphilis and, although usually unrecognized, hepatitis B. The etiology and epidemiology of the last-named disease were quite unknown at that time, but in a remarkably perceptive paper Lürman (1885) concluded that an epidemic of 191 cases of jaundice among some 1200 employees in a factory in Bremen, Germany, in 1883-1884 was probably associated with the mass vaccination of the staff with a particular batch of humanized glycerolated lymph.

The danger of vaccinal syphilis was recognized in Italy as early as 1814, and soon after that in other countries. Particularly dramatic was an episode at Rivalta, Italy, in 1861, in which 44 out of 63 children

### Jenner's Critics

Jenner was not without faults or without critics. His principal biographer, Baron (1838), was adulatory in his attitude; Creighton (1887, 1889) was violently condemnatory and Crookshank (1889) mildly critical. More recently, Razzell (1977a) entered the controversy with a book entitled *Edward Jenner's Cowpox Vaccine: the History of a Medical Myth*, to which Baxby (1981) has produced a rejoinder.

Many of the specific comments made by these and other critics have some substance. Both Creighton and Crookshank were particularly critical of Jenner's adoption (in the published paper of 1798 but not in the draft submitted earlier to the Royal Society) of the term "*variola vaccinae*"—cow smallpox—which they held was a false name, designed to mislead. Creighton could see no value in Jenner's contribution, except in so far as it led to Woodville's vaccine, and could discern many disadvantages, especially the danger of transmitting syphilis by arm-to-arm vaccination. Razzell holds that the material used for vaccination, at least after Jenner's original experiments, was not derived from cowpox but was an attenuated strain of variola virus and thus vaccination was really an extension of variolation.

This is not the place to adjudicate on these controversies; Baxby (1981) discusses them at length. It seems to the present authors that, whatever its shortcomings and Jenner's failings, publication of the *Inquiry* and the subsequent energetic promulgation by Jenner of the idea of vaccination with a virus other than variola virus constituted a watershed in the control of smallpox, for which he more than anyone else deserves the credit.

vaccinated with material from a child with unrecognized syphilis acquired overt syphilis; several died and some infected their mothers and nurses. Grön (1928) lists several other episodes, and Creighton (1887), a particularly bitter critic of Jenner, even suggested that "the real affinity of cowpox is not to the small-pox but to the great pox".

#### *Shortages of cowpox virus*

For reasons which have only recently become apparent (see Chapter 29), cowpox, as a disease of cows, was a sporadic disease, as Ceely (1842; quoted in Crookshank, 1889) accurately described. It was very rare in certain parts of Great Britain and some other countries of Europe, and its occurrence from year to year varied unpredictably. Thus it was not always easy to have access to a cow with lesions at the right stage for the direct vaccination of man. Jenner recognized this problem and sought to overcome it by using arm-to-arm vaccination, a method that was widely adopted (see Plate 6.14A). Arm-to-arm vaccination continued to be practised in England until 1898, when it was banned, as far as public vaccinations were concerned. But it was not always possible to maintain a chain of infection in children, so that recourse to animal sources was still necessary. Further, the potential problem of vaccinal syphilis was still present, if human sources were used for vaccination. Another problem was that vaccine was thought to lose effectiveness after having been maintained for a prolonged time by arm-to-arm vaccination (Ballard, 1868).

One alternative source recommended by Jenner was material from the lesions of horses suffering from a disease called "grease". This

is an inflammation of the fetlocks and is caused by a variety of agents, a rare one being horsepox virus, which usually produces lesions on other parts of the body (face, vulva) as well (Crookshank, 1889; see Chapter 2, Plate 2.15). Loy (1801) demonstrated that virus obtained from lesions on the hand of a man who had been treating horses suffering from grease, and material obtained directly "from a sore in the heel of a horse with the Grease", produced typical vaccine lesions in children and lesions like cowpox on the teats of inoculated cows. He showed that children inoculated with this material resisted variolation.

In 1817, equine virus supplied to the National Vaccine Establishment was widely distributed in Great Britain (Baron, 1838), and horsepox was also used as a source of vaccine in continental Europe. Chaveau (1866) believed that in any case horsepox was caused by the same virus as cowpox, although it was an even less common disease.

#### *Production of vaccine in calves*

For some time "retrovaccination" was practised, a procedure that consisted in taking the virus from human lesions back to the cow, which was then used as a source for further arm-to-arm vaccination. This was done primarily to maintain the potency of the vaccine, rather than providing a source of vaccine for distribution and use. The use of animals as a method of vaccine production on a large scale, which overcame problems of vaccinal syphilis and of the loss of vaccine sources, was developed in Italy, which had long shown an interest in vaccination. As early as 1805 Troia

### **Horsepox as a Source of Vaccine Lymph**

In 1817 Jenner appears to have replaced vaccination by "equination" and stocks of virus from cases of horsepox were supplied to the National Vaccine Establishment and widely diffused. Crookshank (1889) concludes a long commentary on horsepox as follows: "In this country, it is more than probable that some of Jenner's stocks of equine lymph are still in use; but equination is not wittingly practised, for it is commonly supposed that all the lymph employed for the purposes of vaccination has been derived from Cow Pox. In France, on the other hand, it is extensively employed. M. Larget informed me that at the Animal Vaccine Station at Bordeaux the lymph which gave most satisfaction was derived from the horse, and that he had been able on two occasions to renew his stock from equine sources."

NATIONAL LIBRARY OF MEDICINE, BETHESDA

**Plate 6.12.** Wood engraving from *Harper's weekly*, 23 April 1870, showing a general vaccination day at the Paris Academy of Medicine. Arm-to-arm vaccination had been superseded by vaccination from the cow after the discussions of the Medical Congress of Lyons in 1864.

in Naples was employing calves as a source of human vaccine, and Galbiati (1810) continued the practice. Then in 1840 Negri in Naples carried the virus continuously in calves.

Use of the calf as a source of vaccine appears to have been confined to Italy until the Medical Congress of Lyons in 1864, when there was heated criticism of vaccination on the grounds that the method of maintenance and production of vaccine then practised in France—namely arm-to-arm vaccination—carried a serious risk of transmitting syphilis. In this discussion, Dr Viennois and Professor Palasciano spoke about the calf as a source of virus, as practised in Italy (Congrès Médical de Lyon, 1864). Dr Chambon and Dr Lanoix immediately arranged for the delivery of a calf

incubating vaccinia to be sent to Paris from the Neapolitan Institute and henceforth the use of calf vaccine gradually extended through France (Depaul, 1867). Belgium adopted it in 1865, and by 1884 the German Royal Commission on Vaccination recommended it in Germany (Hime, 1896). The Netherlands and many states of the USA followed suit. Great Britain was one of the last countries to adopt the practice. Its use there was initiated in 1881, but arm-to-arm vaccination continued to be popular until it was finally banned in 1898 (Table 6.3; Dudgeon, 1963). As late as 1896 Hime felt obliged to devote considerable effort to justifying the practice of “animal vaccination”.

The manner of inoculation consisted in making multiple insertions on a shaved area

on the skin of a calf (Plate 6.13), vaccine being reaped from the separate pocks found at each insertion site on the 5th day after inoculation by expressing the fluid and, as Hime (1896) recommended, scraping the surface of the pock. The material expressed was ground in a mortar and suspended in glycerol, a practice embarked on empirically in Italy in Negri's day, and supported by Koch in Germany. In Great Britain considerable credit was given to Copeman (1899; see also McNalty, 1968), who demonstrated that glycerol was not only a convenient fluid for suspending vaccine, in terms of its clarity and its viscosity, but was also bactericidal though not virucidal (Copeman, 1892).

An important feature of the first hundred years of vaccination was that vaccine production was conducted without any sort of state control. "Vaccine parks" were established by all and sundry, individual physicians maintained their own stocks of "humanized" vaccine by arm-to-arm inoculations, and Hime (1896) complained "The country [Great Britain] is flooded with cheap stuff 'made in Germany' and elsewhere, of unknown nature or origin. It is cheap and therefore sells." In Great Britain the labours of the Royal Commission on Vaccination (Great Britain, 1898) resulted in the Vaccination Act of 1898, which prohibited arm-to-arm vaccination by public vaccinators and undertook to supply them with glycerolated calf lymph. However, it was not until 1925 that regulation of the quality of vaccine was firmly established with the promulgation of the Therapeutic Substances Act (Hutchinson, 1946).

#### *Theological and philosophical objections*

Some churchmen had taken strong positions in controversies about variolation, both

Plate 6.13. Production of vaccine in calf, 5 days after inoculation. (From Depaul, 1867.)

for and against. It was much the same with vaccination. In Italy, priests led processions of people to vaccination sites to be vaccinated; in Bohemia village priests reminded parents of their responsibility not to neglect the vaccination of their children, and in Germany, Great Britain and Switzerland some clergymen vaccinated people themselves. Vaccination was endorsed by the Pope during an epidemic of smallpox in Rome in 1814.

On the other hand, some members of the Church raised objections that vaccination was interfering with the will of God and that smallpox was sent to chasten the population. There were objections to the inoculation of humans with a disease of animals, and popular cartoons depicted people growing horns or tails after being vaccinated (Plate 6.15B).

More serious philosophical objections emerged from the mid-19th century onwards, especially in Great Britain, when efforts to make vaccination compulsory conflicted with growing sentiments favouring personal freedom of choice. Before the era of bacteriology, there was no generally accepted scientific basis for the theory of infection by contagion. Anticontagionists and antivaccinationists tended to be liberal re-

formers who fought for individual freedom against what they saw as despotism and reaction; both quarantine and vaccination were equated with the restrictions of unheeding officialdom.

Although Parliament in Great Britain was slow to introduce legislation on vaccination,

possibly because of the belief that it was important that the poor should not be protected at public expense (Chase, 1982), and because of liberal antivaccinationist sentiment, firm action was taken quite early in several other European countries. Vaccination was made compulsory in Bavaria in 1807,

### Resistance to Compulsory Vaccination in Great Britain

"The Vaccination Acts of 1840, 1841 and 1853... made [vaccination] successively universal, free, non-pauperising and, finally, compulsory. The Acts of 1861, 1867 and 1871 made vaccination enforceable by the appointment of Vaccination Officers, and finally compelled enforcement by making such appointments mandatory... the Act of 1867 permitted parents to be fined repeatedly until the child was vaccinated... the Act of 1871... made negligent parents liable both for non-compliance with the Act and for disobedience of a court order. In default of fines and costs, parents were sometimes committed to gaol and household goods were distrained for sale. As incidents of bona fide opposition to vaccination arose, the severity with which the law was enforced and the weight it laid upon the poorer classes attracted more attention. Gradually, individuals found organised means of expressing their discontent. Such opposition merged with the rising tide of working-class opinion and with the efforts of radical reformers who saw in the vaccination question the embodiment of impersonal and uncompromising governmental intervention in the daily life of the individual... Sanitary reformers of the era were largely united in the belief that enforced 'cleanliness' was a prerequisite to social 'godliness' and a sufficient defence against disease and while many accepted vaccination as a useful, ancillary instrument of prevention, they could not agree with the implicit assumption of 'specificity', and were reluctant to see it impede or replace the elimination of foul air, overcrowding and filthy streets.

"The [subsequent] development of the antivaccinationist movement can be seen in five distinct phases. First, sporadic Radical outbursts in London and the North led during the seventies to the formation of the Society for the Suppression of Compulsory Vaccination in London... The second phase of activity, under the Cheltenham National Anti-Compulsory Vaccination League, extended the movement to the rural population and the agricultural middle classes. When League intrapolitics and its limited programme failed to make an impact on national opinion, a more extensive campaign was begun. This came about in the third phase, with the establishment of a new London Society for the Abolition of Compulsory Vaccination. The highly co-ordinated pressure group tactics of this Society unified support and helped to secure Government inquiry into the vaccination question. The actions of this group in the period 1880-89 prepared the ground for the fourth phase which emerged in the nineties, when the London Society, using the Report of the Royal Commission on Vaccination as a manifesto, amalgamated antivaccinationists into a new National Anti-Vaccination League, and pressed for remedial legislation. The fifth phase, beginning in reaction to administration abuse of the conscientious objection provision of the 1898 Act, receded with the League's decline after 1907, when its final objectives were essentially achieved.

"In retrospect, the movement was part of a wider public reaction against the advance of 'new science' and scientific medicine. Fear, distrust and the human tendency to cherish 'natural' methods of treatment and 'sanitary' methods of prevention could be overcome only by educational means. This required the active co-operation of physicians and lawyers in supervising the administration of compulsory law which had, historically, been accepted naively by Parliament. This co-operation was noticeably absent at this critical interface of law, medicine and public opinion." (MacLeod, 1967.)

in Denmark in 1810, in Bohemia in 1812, and in Sweden in 1816.

#### *Duration of immunity following vaccination*

Jenner is regarded as the father of immunology, but it would be a mistake to believe that he interpreted the resistance to smallpox conferred by vaccination as an immunological phenomenon, as now understood. Rather he saw it as a change in the constitution that rendered an individual resistant to smallpox forever. Jenner maintained this belief until he died in 1823, and explained the increasing number of cases that occurred as time passed since vaccination as being due to "imperfect" vaccination with "spurious cowpox", or for some other reason. Jenner was right in noting that pock-like lesions on the teats of cows could be due to agents other than cowpox (see Chapter 29) but wrong in believing that immunity to smallpox was absolute and lifelong. Jenner's fallibility on this issue was exploited by antivaccinationists opposed to all vaccination, until revaccination provided the solution.

Recognition of the need for revaccination came much earlier in continental Europe than in Great Britain, where the official attitude throughout the 19th century was that vaccination in infancy gave lifelong protection. Thus, in Great Britain the 1840 legislation providing for infant vaccination, and subsequent Acts providing for compulsory infant vaccination, were founded on the false Jennerian concept that infant vaccination produced lifelong immunity, so that revaccination was unnecessary. As late as 1898 the Royal Commission on Vaccination (Great Britain, 1898) stated that only in very exceptional circumstances did infant vaccination not give lifelong protection.

On the continent of Europe and particularly in Germany, the need for revaccination was recognized early, with dramatic results in countries in which revaccination was compulsory (see Table 6.4).

#### **Evidence for the Efficacy of Vaccination**

The initial response to the idea of vaccination was based on an optimistic extrapolation of Jenner's meagre experimental results, its close resemblance to variolation, in principle and in the production of a local lesion, and the

deeply felt need to find something better than variolation, which usually brought on a severe disease and could cause outbreaks of smallpox in uninoculated contacts. This is well expressed in a letter dated 2 August 1798 from Cline, who performed the first vaccination in London, in July 1798, to Jenner (Baron, 1838):

"I think the substituting of cow-pox poison for the small-pox promises to be one of the greatest improvements that has ever been made in medicine: for it is not only so safe in itself, but also does not endanger others by contagion, in which way the small-pox has done infinite mischief. The more I think on the subject the more I am impressed with its importance."

After Jenner's initial publication in 1798, Woodville and Pearson in London and others in Germany, Italy and the USA lost no time in carrying out challenge inoculations that far exceeded in number those that Jenner had performed. Then followed growing experience of the immunity of vaccinated persons to natural smallpox. Because of its very obvious advantages, and because it built on the practice of variolation, established in Europe and the Americas for some 80 years, vaccination was adopted throughout the world—and very rapidly. For example, Jenner stated that by 1801 over 100 000 persons had been vaccinated in Great Britain, whereas by 1730, 8 years after the introduction of variolation, less than 1000 people had been variolated in Great Britain and North America.

As more and more people were vaccinated, smallpox mortality declined dramatically and for some decades remained low. Such epidemics as did occur were less severe and less frequent than in the 18th century. Where good statistics were kept, as in Geneva (Perrenoud, 1980) and Denmark and Sweden (Moore, 1817), it was seen that the numbers of reported deaths from smallpox fell to unprecedentedly low levels. Not only did the morbidity and mortality decline dramatically, but the cases that did occur were almost always in unvaccinated persons. There was no logical explanation for this change except the introduction of vaccination.

Faced with this evidence, the governments of several countries decided that protection against smallpox was not something that could be left to individual choice. First, variolation, as a potential source of smallpox, was banned in Russia in 1805, in Prussia in 1835 and in Great Britain in 1840 (Edwardes,

1902). Then vaccination, usually of infants, was made legally compulsory in Bavaria (1807), Denmark (1810), Norway (1811), Bohemia and Russia (1812), Sweden (1816) and Hanover (1821). Great Britain and France were to follow much later, in 1853 and 1902 respectively. Of course, having a law on the statute books and enforcing it were two different matters, especially as the problem of the large-scale production and distribution of vaccine was not solved until the latter half of the 19th century. Nevertheless, the evidence for the efficacy of vaccination, provided by countries in which it was compulsory and in which the law was enforced, was compelling. Edwardes (1902) summarized much of this evidence in his excellent little monograph.

The figures for Sweden, which has some of the earliest reliable statistics, are shown in Fig. 6.1. Vaccination began in Sweden late in 1801 and was made compulsory in 1816. From about 1802 onwards there was a dramatic change in the 18th century pattern of major epidemics (3000–7000 smallpox deaths per million population) every 5 years or so, against a background of high endemicity (600–800 smallpox deaths per million population). The epidemic waves subsided and from about 1810, as vaccination became more widespread, the figures fell to unprecedentedly low levels. Six years after the institution of compulsory vaccination the ratio of smallpox deaths per million population reached a single figure—over a hundredfold reduction from the previous endemic level. After that, in spite of the maintenance of a reasonably high level of infant vaccination, the death rate rose again and epidemics recurred, although at a tenth the amplitude and at longer intervals than in the 18th century.

This pattern occurred elsewhere in Europe, wherever vaccination coverage was reasonably good. After a period of freedom for some 20 years, smallpox began to recur in pandemics affecting most of Europe in 1824–1829 and 1837–1840, with mortalities that were low by 18th century standards but much higher than the general public or the health workers of the time regarded as tolerable. Further, the pattern of the epidemics had changed. During the 18th century the high level of endemicity had ensured that most adults living in cities were immune as a result of childhood infection or perhaps of variolation; urban epidemics occurred primarily in children. Now, where

Fig. 6.1. Smallpox deaths per million population in Sweden between 1722 and 1843, showing from 1820 onwards the proportion of newborn children who were vaccinated in infancy. (Based on Edwardes, 1902.)

infant vaccination was widespread, there was a higher rate of illness in adults than in children. And even more than in the past, smallpox deaths occurred among the lower classes of society, who had less access to vaccination.

It was clear that Jenner's belief that one inoculation with cowpox gave permanent protection against smallpox was wrong. An increasing number of cases occurred in vaccinated adults, but with a much lower case-fatality rate than before, and a different and milder symptomatology, which caused difficulties in diagnosis (Monro, 1818). One suggested answer, in Great Britain, was to revive variolation (Creighton, 1894). A safer, more sensible, solution was to recommend revaccination. The German states took the lead, and revaccination was introduced in Württemberg in 1829; other states, beginning in 1833, instituted the compulsory vaccination of military recruits. In the Prussian army, the number of deaths from smallpox, which had averaged 88 per year in 1831–1834, dropped to single figures and averaged less than 2 per year for the next 30 years.

The great European epidemic of 1870–1871 (see Chapter 5) provided a salutary lesson that smallpox was not yet under control, but the very much lower incidence in

the Prussian than in the French army demonstrated the value of vaccination and revaccination. Germany took these lessons to heart and in 1874 promulgated a vaccination law requiring that every child should be vaccinated during the 2nd year of life and that every schoolchild should be revaccinated during the 12th year, unless an attack of smallpox, or a successful vaccination, had occurred within the previous 5 years. The results, when compared with the prevailing situation in Austria, in which general conditions were similar but revaccination had not been introduced, were dramatic (Table 6.4) and hardly require comment.

A hundred years after Jenner's experiment with James Phipps, the *British medical journal* (1896) published a Jenner memorial number and medical journals in many other countries published special articles on Jenner and vaccination (Pfeiffer, 1896; *Index medicus*, 1897). Russian translations of all of Jenner's publications on vaccination were also produced in 1896 (LeFanu, 1951).

A few years later Edwardes (1902) published his compendium of statistics. All in-

vestigations illustrated that the practice of vaccination and revaccination, properly conducted, was a brilliant success; Jenner's prediction (see Plate 6.8) that smallpox could be eradicated by vaccination was correct. Almost 80 years were to elapse, however, before *global* eradication was achieved, and practices additional to mass vaccination, which in an elementary form had antedated the concepts of variolation and vaccination, had to be invoked—namely, isolation and containment.

### CONTROL BY ISOLATION AND QUARANTINE

One other method of control began even before variolation and, combined with vaccination, furnished the ultimate method for the control of smallpox—namely, isolation and, for travellers by sea, its equivalent, quarantine. It was believed from early times, first with leprosy and then with plague, that it might be possible to avoid certain diseases by ensuring that no contact occurred between

diseased and healthy persons. The practice of designating huts or villages in which severe infectious diseases such as plague or smallpox were present, as an indication that they were to be avoided, appears to have arisen independently among several different peoples in Africa, Asia and Europe. It was difficult to achieve the efficient isolation of cases where diseases were endemic, but relatively easy when they were present on ships that approached disease-free ports. Thus the quarantine of ships developed earlier and more effectively than did effective isolation of smallpox patients on land.

The scientific underpinning of the concepts of isolation and quarantine had to await the enunciation of the germ theory of infectious diseases by Pasteur and Koch, in the latter half of the 19th century, but long before this a belief had developed that such diseases were spread by contagion. The best-known early European exponent of this view, for smallpox and measles, was Girolamo Fracastoro of Verona (1478-1553). In a classic book (Fracastoro, 1546) he attributed these diseases to specific seeds, or *seminaria*, which were spread by direct contact from person to person, by intermediate objects, or fomites, or perhaps at a distance, through the air.

### Quarantine for Shipping

At the time of the Black Death, in the 14th century, the Venetians and other trading nations of the Mediterranean recognized that ships sometimes brought plague to their cities, and instituted the practice of isolating travellers and ships suspected of carrying plague for a period that became, after some adjustments, 40 days—hence the word quarantine (Gerlitt, 1940).

The idea of using quarantine to prevent the entry of smallpox came most readily to European colonists in places previously free of smallpox, notably North America and Australia. Smallpox was endemic in Great Britain when North America was being settled in the early part of the 17th century, and smallpox occurred on several ships during the Atlantic crossing. Later, epidemics of smallpox occurred in Boston, the major seaport at the time, in 1636, 1659, 1666, 1677-1678, 1689-1690 and 1697-1698. Between these times the disease disappeared; the introductions followed the arrival of ships carrying new settlers or slaves with smallpox.

Although the early North American settlers believed no less than their British contemporaries in the notion of pestilence as divine punishment, they were pragmatic enough to invoke quarantine to prevent the entry of smallpox from overseas. By 1647, vessels arriving in Boston from the West Indies with infected passengers or crew were quarantined in the harbour, initially probably for yellow fever (Blake, 1953, 1959), and similar measures were subsequently adopted in New York and other port cities (Tandy, 1923).

Eventually, as the European settlements in North America increased in size, smallpox became endemic and quarantine was no longer relevant. Variolation and subsequently vaccination became more important ways of controlling smallpox. But in Australia and New Zealand, much more sparsely populated and situated much further from other centres of population than North America, smallpox never became endemic and quarantine remained an important method of excluding the disease throughout the 19th and 20th centuries (Cumpston, 1914; see also Chapter 8).

### Isolation of Cases

The isolation of patients on land was more difficult to put into effect than preventing the landing of infected persons from ships. Nevertheless, the colonists in North America attempted this as early as 1662, when an order was issued at East Hampton, Long Island, to prevent the spread of smallpox from local Indians to the town's population (Tandy, 1923). In 1667 the colony of Virginia legislated for the mandatory isolation of victims of smallpox at home.

The idea of isolation to control the spread of smallpox received a considerable stimulus with the popularization of variolation, since it was early recognized that one of the risks of this practice was the spread of smallpox to uninoculated contacts. It therefore became customary to variolate children in groups and keep them in isolation, tended by persons who had already had smallpox, until the scabs fell off. Jenner himself had this experience in 1757, at the age of 8 (Baron, 1838).

By the end of the 18th century some writers had already conceived the idea of controlling smallpox by a combination of variolation on a wide scale and the isolation of smallpox

patients. Haygarth (1793) developed a comprehensive plan involving the periodic variolation of the general public, the isolation of cases, the disinfection of fomites, etc.; a few years later Carl (1799), then Director of the Inoculation Institute in Bohemia, proposed a similar procedure. By 1803 the government of Bohemia required the compulsory notification of cases of smallpox, the isolation of cases and the sterilization or destruction of bed-linen, toys, etc., of smallpox patients (Carl, 1802; Raška, 1976).

Impressed by the example of the "stamping out" of the devastating cattle plague, rinderpest, in Great Britain a few years earlier, Sir James Simpson, famous for his introduction of chloroform for anaesthesia, wrote an article for the *Medical times and gazette* in 1868 (Simpson, 1868), which aroused considerable interest and discussion. In it he developed a proposal for eradicating smallpox and other infectious diseases, such as scarlet fever, measles and whooping-cough, by the isolation of cases. He recognized that his proposals could be most readily achieved with smallpox, because vaccination provided a means of protection for nurses and others who had to remain in contact with patients. His proposed "Regulations" were as follows:

- "1st. The earliest possible notification of the disease after it has broken out upon any individual or individuals.
- "2nd. The seclusion, at home or in hospital, of those affected, during the whole progress of the disease, as well as during the convalescence from it, or until all power of infecting others is past.
- "3rd. The surrounding of the sick with nurses and attendants who are themselves non-conductors or incapable of being affected, inasmuch as they are known to be protected against the disease by having already passed through cow-pox or small-pox.
- "4th. The due purification, during and after the disease, by water, chlorine, carbolic acid, sulphurous acid, etc., of the rooms, beds, clothes, etc., used by the sick and their attendants, and the disinfection of their own persons."

Perhaps the most vigorous advocacy of isolation as a method of controlling smallpox was developed in the city of Leicester, in England, largely as a result of the strength of the local antivaccinationist movement (Fraser, 1980). The essentials were the prompt notification of cases of smallpox, the isolation of cases in the town's Fever and Smallpox

Hospital, and the quarantine of all immediate contacts, with compensation for loss of time from work. Vaccination was not mentioned, and in Leicester there was strong disapproval of compulsory vaccination, and especially of the prosecution of those who refused vaccination on grounds of conscientious objection, until the turn of the century. The system was developed during the 1870s and achieved notoriety in the 1890s. Subsequently, the vaccination or revaccination of contacts was added to the routine procedure (Millard, 1914). This procedure, the "Leicester method" plus vaccination, like the proposals of Haygarth and Carl long before, anticipated the surveillance and containment strategy of the World Health Organization's Intensified Smallpox Eradication Programme.

### The Establishment of Smallpox Hospitals

Dixon (1962) devotes a chapter of his book to the smallpox hospital and traces the history of such hospitals in Great Britain, as well as outlining his views on basic requirements. The notion that a special infectious diseases or smallpox hospital or ward should be an integral part of the control of smallpox arose as recently as the 20th century, except for a

WELLCOME INSTITUTE LIBRARY, LONDON

Many of his early vaccinations, carried out in the presence of cases of smallpox, were associated with generalized rashes, a source of confusion until they were recognized as being caused by variola virus.

few places, such as Leicester (see above), in which such institutions already existed. Prior to that, hospitals were sometimes established in response to epidemics, often of smallpox, as in Quebec in 1639 (Hôtel Dieu) and on frequent occasions in towns in Great Britain. But in general smallpox patients were not admitted to hospitals.

In England, the London Small-Pox and Inoculation Hospital was founded in 1746, initially for the treatment of poor persons with smallpox but soon afterwards mainly as a hospital for subjects undergoing variolation. An Inoculation Institute was established in Brno (Bohemia) at about the same time. Subsequently small private "inoculation hospitals" were set up in most places in which variolation was practised extensively, to prevent the spread of smallpox to susceptible contacts. The London Small-Pox and Inoculation Hospital played an important role in the early days of vaccination, for Woodville worked there (Plate 6.16) (Woodville, 1796, 1799, 1800).

Long before this, the Japanese book *Ishinho*, produced in AD 982, mentioned the establishment of special hospitals for smallpox cases, but it is difficult to interpret their significance. The use of infectious diseases hospitals as part of the machinery for controlling smallpox required an efficient system of notification, which was easier for smallpox than for most other diseases. Notification formed the core of the "Leicester method" and was a most important factor in limiting the spread of smallpox after importations into Europe and North America during the 20th century (see Chapter 23). However, national notification of cases of infectious diseases was not introduced into Great Britain, for example, until 1899, and even an imperfect system of notification required a public health service far more effective than anything that existed during the 19th century. Even in the industrial countries of Europe, therefore, elimination of smallpox was not achieved until well into the 20th century (see Chapter 8).

### INTRODUCTION

By the year 1900 vaccination was in widespread use throughout the industrialized countries as well as in some cities in what were then the colonies of various European powers. Although variolation was no longer practised in Europe and North America, it was still widely employed in many parts of Africa and Asia. Smallpox persisted as an endemic disease in virtually every country of the world (see Chapter 8, Fig. 8.16), although its incidence in the industrialized countries was lower than in previous centuries.

The latter half of the 19th century saw the emergence of microbiology and immunology as scientific disciplines. Because of their familiarity with vaccination, many of the pioneers in these new sciences used vaccinia virus for their studies (see Chapter 2). In consequence, the empirical practices of Jenner and his early followers were placed on a more scientific basis. Vaccine production was no longer the province of the local physician, who had maintained the virus by arm-to-arm transmission, and small local "vaccine parks", but was taken over by factory-type laboratories, the precursors of the great bio-

### Cowpox Virus and Vaccinia Virus

All orthopoxviruses exhibit cross-protection in laboratory animals. Among the orthopoxviruses that infect humans, cowpox and vaccinia viruses usually produce only local lesions, with minimal systemic disturbance, whereas variola and monkeypox viruses cause serious systemic diseases. Jenner's original "variolae vaccinae" was cowpox virus, and during the 19th century, on many occasions, virus for vaccination was derived from lesions in cows and sometimes horses in several European countries. Since the description of the biological characteristics of cowpox virus by Downie (1939a,b), it has been recognized that smallpox vaccines in use then, and probably for many years before the 1930s, consisted not of cowpox virus, but of another orthopoxvirus which had long been called "vaccine virus", but was shown by Downie to have biological properties different from those of cowpox virus (see Chapter 2). Although some smallpox vaccines were still said to be made from cowpox virus during the 1960s, it is doubtful, in the light of evidence from contemporary virological studies, whether this was so.

The origins of vaccinia virus are unknown. It may have arisen as a hybrid between cowpox virus and variola virus, it may have been derived from cowpox virus or some other orthopoxvirus by serial passage under artificial conditions of culture, or, as Baxby (1981) has suggested, it may be the laboratory survivor of a virus that is now extinct in nature. Whatever its origin, vaccinia virus is clearly a distinct species of *Orthopoxvirus*, and DNA maps of different strains of vaccinia virus are remarkably similar to each other and different from those of all other orthopoxviruses, including cowpox and variola virus (see Chapter 2, Fig. 2.7, 2.9 and 2.10, and Chapter 29, Fig. 29.1). However, like cowpox virus in the hands of Jenner and his followers, it provided inoculated subjects with a high degree of protection against smallpox, with little risk to either the individual or the community.

logical products supply houses of the 20th century.

There was a steady improvement in the quality of the vaccine, the methods for its distribution, and the public health infrastructure, which had reached such a level that by the early 1950s endemic smallpox had been eliminated from the industrialized countries of Europe and North America (see Chapter 8). In the decade after the end of the Second World War, several major advances were made in the production and methods of delivery of the vaccine, but further change and innovation were necessary before global eradication was feasible. This chapter summarizes the state of the art of vaccine production and inoculation, and the results of investigations into the complications of vaccination, as these stood in the period between the end of the Second World War and 1967, when the Intensified Smallpox Eradication Programme was initiated.

During the middle years of the 20th century quarantine measures, which had earlier operated on a national basis in some countries (see Chapter 6), were elaborated and applied on a global scale, with the development of the International Health Regulations by the World Health Organization. The

present chapter concludes with an account of the introduction and eventual demise, in 1981, of the International Certificate of Vaccination or Revaccination against Smallpox.

### VACCINE PRODUCTION AND QUALITY CONTROL BEFORE 1967

Jennerian vaccination was the tool with which the incidence of smallpox was reduced and the disease eliminated from many countries of Europe and the Americas during the first half of the 20th century. However, at some time during the 19th century, for reasons which are obscure, the nature of the virus used for vaccination changed, in most parts of the world, from cowpox virus to another orthopoxvirus, which came to be known as vaccinia virus.

As scientific virology developed during the 20th century, it was applied to the study of smallpox vaccine and vaccination, and new methods of preparing, distributing and inoculating the vaccine were developed. The descriptions which follow refer to the best methods and procedures in use for vaccine production before 1967. However, because

### Vaccine Pulp and Vaccine Lymph

By the end of the 19th century arm-to-arm vaccination had been made illegal in many countries and smallpox vaccine was obtained from animal skin. However, technical knowledge of vaccine production was still extremely poor. For example, even in an advanced industrialized country it was recommended that seed lymph could be obtained from (1) "smallpox direct", (2) cowpox, (3) horsepox, sheep-pox, goatpox, swinepox, or (4) vaccinia in the human body (England and Wales, Ministry of Health, 1928a).

Looked at with modern eyes, the production of smallpox vaccine, even in 1966, was a primitive operation. The method of production, in animal skin, made bacterial contamination inevitable, something that would not have been tolerated in a new viral vaccine in the 1950s.

A number of traditional expressions were used to describe the product obtained at different stages of the process: the animal in which the vaccine was produced was called the *vaccinifer*, the material used for its inoculation the *seed*, the material reaped from the scarified skin the *vaccine pulp*, and the clarified suspension obtained from this the *vaccine lymph*. The pulp was a mixture of epidermal cells and leukocytes, plasma, hair, bacteria and the virus. Clarification removed some of the coarser debris, but the vaccine lymph was milky in appearance on account of contamination with fragments of cells and bacteria. Purified virus, at the concentration found in the lymph, would have been a water-clear suspension.

smallpox vaccine was produced in many countries, in which there were wide differences in the degree of scientific and industrial experience and skill, the procedures employed in some countries were much less satisfactory than those described here. Modifications to traditional production and assay methods, and—most important—the international quality control of vaccines, were introduced shortly after the Intensified Smallpox Eradication Programme began operations in 1967 (see Chapter 11).

### Production of Vaccine Lymph

During the first half of the 19th century vaccine was usually made available by arm-to-arm transfer but was sometimes dispatched over long distances dried on threads, ivory tips, or glass slides (see Chapter 6). Cows were first used for the production of vaccine in Italy early in the 19th century; this practice gradually spread around Europe and was universal by the end of the century. Over the years, changes were made in the mode of preparation of both liquid and dried vaccine, but the initial production of vaccine pulp was the same for each.

#### *Choice of vaccinifer*

For historical reasons, calves were first used for vaccine production. During the First

World War, the Lister Institute of Preventive Medicine, in Elstree, Hertfordshire, England, introduced the use of sheep, a practice subsequently adopted in some other countries. Because of their ready availability, water-buffaloes were sometimes used in India, Indochina and Indonesia, and W. A. Collier (1953) considered them to be superior to other species for vaccine production. Attempts were made in several countries to produce smallpox vaccine in chick embryos and in cultured cells, to avoid the bacterial contamination that was inevitable when production was carried out by scarification of the skin of large animals. However, chick embryo vaccines were produced on a commercial scale only in Brazil, Sweden and the state of Texas in the USA, and only in Brazil were they in widespread use in an eradication campaign (see Chapter 12). Except on a very limited scale, tissue culture vaccines were never produced commercially.

During the 1920s the concept was developed that biological products prepared for use in man should be bacteriologically sterile. Legislation was introduced in some of the industrialized countries to regulate the production of vaccines and similar products. At that time smallpox vaccine grown on the flank of calves was already in wide use. Inevitably, it contained some bacteria, but there was no other practicable method of production. Thus smallpox vaccine was the

**Plate 7.1.** The preparation of smallpox vaccine at the Vaccine Production Institute, Dhaka, Bangladesh. **A:** Calves to be used for vaccination were held in quarantine for 7 days. **B:** Four days after scarification, the skin was scraped with a sharpened stainless-steel spoon and the vaccine pulp collected in a jar, for subsequent grinding and centrifugation to yield the vaccine lymph.

only vaccine for which both the public and the health authorities accepted the fact of contamination by exogenous microorganisms. Since bacterial contamination was inevitable, the aim in preparing vaccine lymph was to exclude pathogenic bacteria completely and reduce the level of contamination with the normal skin bacteria of the vaccinifer. Choice of a healthy vaccinifer was clearly of major importance. The requisite veterinary inspection was practised in some countries, but in others animals were bought in the market, or even rented to be returned afterwards to their owners. This last procedure circumvented one of the important precautions recommended by producers in developed countries—namely, that a thorough postmortem examination should be conducted when the animal was killed at the end of the incubation period and the pulp discarded if serious disease was found.

Under optimum conditions, every animal used for vaccine production was subjected to an examination by a veterinarian to ensure that it was free from tuberculosis, skin infection and ectoparasites. Only animals which had been free of fever and any sign of disease for at least 2 weeks were used, and during this observation period the animals were clipped and washed.

#### *Preparation of the vaccinifer*

The proper preparation of the skin of the vaccinifer was one of the most important steps in obtaining a vaccine of low bacterial content. After being anaesthetized or tranquillized, the animals were washed on an area on the flank or belly, preferably one not liable to soiling by excretions, and then shaved extensively enough to permit a reasonably large area to be scarified. Some producers treated the skin with an efficient skin disinfectant, such as a quaternary ammonium compound, and before vaccination the prepared area was well rinsed with sterile distilled water.

#### *Scarification*

The skin was prepared for vaccination by scarification, using the same principle as for the vaccination of humans (see below)—namely, to bring the virus into contact with cells in the Malpighian layer of the epidermis. However, the operation was on a much larger scale, the aim being to produce a confluent take on a large area of the flank and abdomen. The usual procedure was to make a series of parallel scratches about 1 cm apart on the cleansed flank and abdomen of the vaccinifer,

followed by a similar series of scratches at right angles to the first. A wide variety of instruments was used in different laboratories, sufficient force being exerted to produce obvious erythema of the skin, but not bleeding. The prepared skin was then inoculated by rubbing seed virus of high infectivity into the superficial scarifications. Practical considerations limited the extent of the area scarified, because in some countries animals in rather poor health were used, and too extensive scarification might have caused their death.

Two important features which were subject to a great deal of variation in different countries, and sometimes even among different producers in the same country, were the choice of the strain of vaccinia virus and the mode of preparation and maintenance of the seed virus (see below).

#### *Incubation period*

Methods of maintaining the vaccinifer until the lesions were ready for harvest differed considerably. Ideally, the scarified area was loosely covered with a cotton cloth, which was changed at least once each day. In the better laboratories, the pen in which the animal was housed was so constructed that the vaccinated animal could not lie down. It had walls that could be washed frequently and a hard floor on which was placed a slatted wooden platform the length of the animal and sloping gently from front to back; the pen was cleaned thoroughly and often. In some countries, however, the vaccinifers were housed in ordinary stables and sometimes they were even turned out to pasture.

The pulp was harvested before crusts formed on the vaccinated area, at a time when both the viral titre and the quantity of pulp were at their maximum. Workers at the Lister Institute found in the 1920s that the viral yield was about the same on the 4th and 5th days after inoculation, but preferred the 4-day incubation period because the opportunity for bacterial contamination and hair growth was reduced by a day.

#### *Harvest*

The skin was rinsed with warm water, with or without soap, and the pulp was scraped from the skin with a curette, one form of which was made by sharpening the edge of a hemispherical stainless-steel spoon (Plate 7.1 B). If the animals were killed, exsanguination

before scraping ensured a less blood-stained product; if they were not killed, they were usually anaesthetized before scraping. Harvests from individual animals were kept separately in sterile containers closed tightly enough to prevent drying by evaporation, and stored below 0 °C except when being processed.

#### *Seed virus used for inoculation*

The seed viruses used in various laboratories differed with regard to the strain of virus employed and the titre of the inoculum, as well as the methods by which they were maintained.

*Strain of vaccinia virus.* With a procedure that had been in use in many countries for over a hundred years, and with no effort at international standardization, it was not surprising that the strains of virus employed for vaccination in different countries differed in their biological properties. The choice of a particular strain was arbitrary, being based on the history of the vaccine production laboratory concerned. An examination of the situation in 1967 showed that many different strains were then in use (see Chapter 11). This can be understood when it is realized that during the 19th century vaccine production was an unregulated activity, undertaken by a large number of "backyard" producers. For example, as A. C. Hekker has commented (personal communication, 1981), in 1875 there were about 15 "*parcs vaccinogènes*" in a country as small as the Netherlands, with at least 1 in every province. By 1900 the number had been reduced to 3—in Amsterdam, Groningen and Rotterdam respectively. Finally, in 1954, production was centralized in the National Institute of Public Health, Bilthoven. The situation was similar in many other countries—for example, in Great Britain, where lymph maintained by arm-to-arm inoculation was used until the 1890s.

Since different strains of vaccinia virus vary considerably in their biological properties (see Chapter 2) and since the properties of the viral strain were probably important in determining the differences found in the rates of occurrence of postvaccinal encephalitis in different countries (see Table 7.8), this was not a trivial matter. However, no steps were taken to recommend internationally which vaccinia strain should be used for vaccine production until after 1967 (see Chapter 11), although some countries in which postvac-

### The Stability of Vaccinia Virus

Stocks of all viruses, even after cloning (i.e., being grown from a single plaque or pock and thus a single viral particle), contain a small proportion of mutant virions (see Chapter 2). Most attenuated live virus vaccines were developed by selecting for certain of these mutants by continued serial passage of concentrated viral suspensions in a novel host. With an agent that was suitable to start with, such as vaccinia virus, the reverse sometimes occurred. The early vaccinators believed that serial passage in humans "weakened" the vaccine, and they resorted to periodic "retrovaccination"—i.e., passage of the virus in cows—to enhance its potency (see Chapter 6). Subsequently, some manufacturers observed that continued serial passage in calves led eventually to a fall in the take rates of the vaccine in man, although others (e.g., W. A. Collier, 1953) found that potency was maintained throughout 35 serial passages in water-buffaloes.

Manufacturers sought to overcome the fluctuations in potency by periodic passage of the seed virus in other animals, usually the rabbit but sometimes monkeys, donkeys or even human subjects. These manipulations were rendered unnecessary by the development of the "seed lot" system.

cial encephalitis had been a serious problem had changed their production to the less pathogenic Lister strain before this.

*Titre of inoculum.* All authorities agreed that it was desirable to use an inoculum with as high a titre as possible. Two methods for measuring the titre had been used after the Second World War: scarification of the skin of a rabbit and pock counts on the chorioallantoic membrane of the chick embryo. The rabbit-skin assay, which consisted of a series of scarifications of 10-fold or sometimes 3-fold dilutions of the material under test, was not very precise, hence many producers could not make accurate estimates of the titre of either their inoculum or their product. Pock counting, although early shown to be very suitable for the assay of vaccinia virus (Keogh, 1936), did not come to be widely used by vaccine producers until the 1950s.

*Maintenance of seed virus.* As recently as 1966, many manufacturers still used some of the vaccine lymph prepared for distribution as the inoculum for the next series of vaccinifers, a procedure that over the years involved a large but unknown number of serial passages of the virus in these animals. Other manufacturers passed the virus in the skin of man or the rabbit after a certain number of subcultures in calves, or alternately in vaccinifer and rabbit. Meeting in 1958, a WHO Study Group on Requirements for Smallpox Vaccine (1959) recommended the use of the seed lot system. This involved, in principle, laboratory maintenance at refrigerator temperature of large stocks of a primary seed lot of a suitable

preparation of vaccinia virus. From this primary seed lot enough virus had to be prepared for the production run. Depending on its titre, the extent to which it multiplied and the number of vaccinifers used, the primary seed was passaged once or several times by the scarification of single calves to obtain the seed lot for the production run. The number of such serial passages of the virus in the vaccinifer was usually restricted to 5. With this method, possible alteration of the strain could be limited, the chance of extraneous contamination was reduced, and the inoculum could be standardized in terms of viral concentration and freedom from contamination.

### Preparation of Liquid Vaccine

Traditionally, the vaccine pulp was processed so as to remove some of the extraneous material and reduce the bacterial count, and it was then dispersed as a liquid suspension called vaccine lymph.

#### *Clarification of the vaccine pulp*

The semisolid pulp was usually ground into lymph by comminuting it in a grinder, or later by homogenization in a blending machine. For this purpose it was usually mixed with 40–60% glycerol. Storage of the glycerolated homogenate at low temperature over a period of months led to a steady fall in the number of viable bacteria, but it was later

found that the same result could be more rapidly achieved by the addition of phenol (see below). Periodically bacteriological tests were made to determine when the lymph was suitable for distribution.

#### *Use of glycerol*

The introduction of glycerol to "stabilize" the vaccine virus and at the same time prevent bacterial multiplication was regarded as a major step forward in lymph production. This procedure made it feasible to change from arm-to-arm vaccination or the use of an itinerant vaccinated cow (see Chapter 6, Plate 6.12) to the distribution of liquid vaccine in capillary tubes.

Glycerol had three advantages: it acted as an antibacterial preservative, it helped to make the vaccine stick to the skin, and it permitted the maintenance of the vaccine in liquid form at  $-10^{\circ}\text{C}$  and thereby ensured the long survival of active vaccinia virus. It also prevented ice formation, a process which, in the presence of phenol (contained in nearly all smallpox vaccines), led to the reduction of viral infectivity.

However, although Copeman (1892, 1899) had claimed that glycerol was bactericidal but not virucidal, subsequent work showed that at temperatures above  $0^{\circ}\text{C}$  it inactivated vaccinia virus rather rapidly. The deleterious effect of glycerol was of little importance in countries with temperate climates, especially if good refrigeration was available, but it was an important cause of vaccine failure in tropical areas.

#### *Use of phenol*

The bacterial count in glycerolated pulp stored in the refrigerator fell off very slowly. Several months were usually required before it was low enough to allow the vaccine to be issued for use, and repeated testing was necessary during this period. The procedure could be greatly accelerated by adding phenol to a final concentration of 0.5%, a procedure originally recommended by Gins (1924) and Lehmann (1937) and popularized by McClean (1949), whose protocol was as follows: Material harvested from the sheep was ground with twice its weight of a 1% solution of phenol in distilled water. After this had stood at  $22^{\circ}\text{C}$  for 48 hours, glycerol, equal in amount to the phenol solution, was added, so

that the final concentration of phenol was 0.4%.

#### *Mode of distribution*

Liquid vaccine was usually dispensed in glass or, later, plastic capillary tubes, in single-dose lots or in amounts sufficient for about 20 vaccinations.

### **Preparation of Dried Vaccine**

Liquid vaccine was satisfactory in temperate countries with well-developed health services, good transportation networks and reliable refrigerator capacity. Endemic smallpox was eliminated from Europe and North America by vaccination with liquid glycerolated vaccine, even though its potency was sometimes lower than desirable. At this time many authorities favoured the use of multiple sites of insertion (usually 2 or 4), a procedure which continued up to the 1960s in India and which sometimes produced a satisfactory take even with a substandard vaccine. However, liquid vaccine was totally unsatisfactory for tropical countries, as reports from medical officers in those areas attested. In 1919, for example, the complaint was made in Africa that even for primary vaccination "only 7-20% positive results were obtained with the best vaccine" (Tanganyika Territory, 1920). Likewise, in Madras, Hobday et al. (1961) obtained a 27% take rate in revaccinations with fresh liquid vaccine compared with a 63% take rate with freeze-dried vaccine. Because of its low heat stability, health authorities sometimes went to great trouble to try to maintain the potency of liquid vaccine. In Peru, for example, in the period before freeze-dried preparations became available, vaccine was carried in the field in kerosene refrigerators mounted on the backs of mules (C. Quirós, personal communication, 1984).

#### *Air-dried vaccines*

It was recognized very early that dried vaccine often survived far longer than liquid vaccine when both were maintained at ambient temperatures, and Jenner himself distributed vaccine dried on threads or between glass slides. Over the years a variety of methods for drying liquid vaccine were employed (L. H. Collier, 1954). Among the more

BY COURTESY OF C. QUIROS

effective were those devised by Camus (1909), working at the Vaccine Institute in Paris and concerned to produce an effective vaccine for use in French colonies in the tropics, and by Otten (1927), working in Batavia (Jakarta). Camus placed vaccine pulp in a thin layer under an evacuated bell jar, in the presence of sulfuric acid. The pulp was cooled and shaded from light, and drying was complete within a few hours. In tests in western Africa, after transport at ambient temperatures, it gave take rates in different trials of 66–100%. Otten used a similar procedure: buffalo lymph was dried *in vacuo* over sulfuric acid, at room temperature. Subsequently the ampoules were attached to a manifold and sealed under vacuum (Plate 7.3A). Although the results were variable, the majority (80%) of preparations of such dried vaccine produced takes in 75–100% of primary vaccinees, after storage at room temperature in Batavia for 16–30 months or at 37 °C for 12 months (Otten, 1932; W. A. Collier, 1953).

Otten's vaccine was an important factor in achieving the elimination of smallpox from the Netherlands East Indies (now Indonesia) in 1937 (see Chapters 8 and 13). However, there was considerable batch-to-batch variation, the vaccine was often heavily contaminated with bacteria, and it was difficult to reconstitute. Further, the technique did not lend itself readily to large-scale production.

#### *Freeze-dried vaccines*

In 1909 Shackell reported an improved method of drying biological materials, based on the fact that H<sub>2</sub>O could pass directly from a solid to a gaseous state. He deep-froze the biological material and sublimated it *in vacuo*. During the First World War, Wurtz & Camus (1919) produced a freeze-dried vaccine which was packed in tubes under vacuum. Samples prepared by this method were active after several weeks at 37 °C and, when transported from France to Côte d'Ivoire, Guinea and French Guiana, gave take rates of 85–100% (Fasquelle & Fasquelle, 1949) (Plate 7.2A).

Approximately 10 million doses of this dried vaccine were sent every year between 1920 and 1940 to the French colonies in Africa for the smallpox vaccination campaign, and the Vaccine Institute in Paris continued to supply it to the francophone countries of Africa until 1966, in amounts ranging from 4 to 12 million doses annually (J. Fasquelle, personal communication, 1983).

During the eradication programme in western Africa in 1967 (see Chapter 17), it was found that smallpox was less of a problem in countries that had been French colonies, in part because of their previous use of freeze-dried vaccine.

Meanwhile, from the 1930s onwards various laboratory workers in other countries had adopted freeze-drying for the preservation of vaccinia virus (Rivers & Ward, 1933, 1935; Lloyd & Mahaffy, 1935; Hahn, 1951; L. H. Collier, 1951). The technology was substantially improved by Flosdorf & Mudd (1938). A freeze-dried vaccine developed by Kaiser (1937, 1942) was said to have been used extensively by the German army during the Second World War (cited by L. H. Collier, 1954).

In 1948, the year in which the World Health Organization was established, a WHO study group on smallpox vaccine met in Paris and reported to the First World Health Assembly that freeze-dried vaccine such as that prepared at the Paris Vaccine Institute (using the method developed by Wurtz & Camus) had proved to be an effective heat-stable vaccine in the French colonies for a number of years. Stimulated by these reports, Dr Fred L. Soper, then Director of the Pan American Sanitary Bureau, encouraged the United States National Institutes of Health to carry out studies on appropriate methods for the production of freeze-dried smallpox vaccine, in order to fulfil the proposal made by the Executive Committee of the Pan American Sanitary Organization in 1949 that all countries in the Americas should cooperate in national programmes designed to eradicate smallpox (Soper, 1966). The technical investigations were undertaken by the Division of Laboratories, Michigan Department of Health, then a leading producer of glycerolated liquid vaccines (Ducor, 1947). They resulted in the development of a method for freeze-drying vaccine that had been dispensed in 0.5-ml lots in Pyrex tubes (Hornibrook & Gebhard, 1951), using a sulfuric-acid drier (Plate 7.2B) developed by Hornibrook (1949). Peru was the first country in the Americas to use this process on a commercial scale, beginning in October 1953.

In June 1952, WHO organized comparative studies on the heat stability of freeze-dried vaccine produced by the Vaccine Institute, Paris, the State Serum Institute, Vienna, the Division of Laboratories, Michigan Department of Health, Lansing, USA, and the

**Plate 7.4.** Leslie H. Collier (b. 1921). As a graduate student at the Lister Institute of Preventive Medicine, Elstree, Herts., England, in the early 1950s Dr Collier developed the method of freeze-drying of vaccinia virus that was subsequently adapted to large-scale freeze-dried vaccine production in many laboratories throughout the world.

Pasteur Institute, Bandung, Indonesia. The tests were carried out in the State Serum Institute, Copenhagen, the Division of Laboratories, Michigan Department of Health, the Vaccine Institute, Paris, the Lister Institute of Preventive Medicine, Elstree, and the New York City Department of Health. No laboratory performed the tests on vaccine that it had itself produced. The results showed that the heat stability of the vaccine provided by the Michigan Department of Health was the best of the 4 tested.

The large demand for human plasma proteins for use in the Second World War had led to further advances in the technology of freeze-drying, notably the introduction of a centrifugal freeze-drying apparatus (Greaves, 1946). L. H. Collier (1951), working at the Lister Institute as a graduate student under the direction of D. McClean, applied this technique, with the addition of peptone as a stabilizing agent, to the preservation of vaccinia virus and subsequently developed it for large-scale commercial production (L. H. Collier, 1955). WHO decided to conduct an additional test to compare the new Lister Institute vaccine with the freeze-dried vaccine from Michigan. Samples maintained at

37 °C and 45 °C for various periods were titrated by pock counting on the chorioallantoic membrane and by scarification in rabbits and tested by primary vaccination of Royal Air Force personnel (Cockburn et al., 1957). The Lister freeze-dried vaccine was found to give 100% successful takes after storage for 64 weeks at either 37 °C or 45 °C. The Michigan vaccine was much less heat stable, the take rate falling to 72% after 16 weeks and 10% after 32 weeks at 37 °C (Table 7.1), and to 47% after 4 weeks at 45 °C. The results of titration of the two vaccines by pock counting on the chorioallantoic membrane, in an independent laboratory, were consistent with these results, in that the Lister vaccine maintained its titre whereas that of the Michigan vaccine fell off steadily after storage.

As further modified by C. Kaplan, by the substitution of fluorocarbon treatment for differential centrifugation as a method of partial purification, L. H. Collier's method was eventually adopted by WHO for the global smallpox eradication programme (see Chapter 11).

Subsequently, freeze-drying technology was greatly improved for the large-scale commercial production of vaccine, particularly in the methods of filling and sealing ampoules. The availability of a method for the long-term preservation of vaccine in tropical climates was an important factor in encouraging countries to participate actively in the global smallpox eradication programme.

Vaccine pulp destined for freeze-drying was prepared as for liquid vaccine, except that glycerol was not added. In some laboratories it was diluted or concentrated according to its potency on assay. In order to reduce bacterial contamination to an acceptable level, phenol was added to the bulk solution of the vaccine so that its final concentration did not exceed 0.5%.

Before 1967, the bulk solution was put into special ampoules or vials containing 0.25, 1.0 and 5.0 ml, corresponding respectively to 25, 100 and 500 doses. These were then placed in a freeze-drier, of which there were two types: the centrifugal drier and the shelf drier (see Chapter 11, Plate 11.7). The former required the use of a secondary drier, which consisted of a number of manifolds mounted over phosphorus pentoxide as a desiccant, while the latter provided both primary and secondary drying and sealing of the containers under vacuum inside the drier.

### Development of Freeze-dried Smallpox Vaccine

"In 1948, I was told by the then Director [of the Lister Institute], Dr (later Sir) Alan Drury, that there was a great need for a smallpox vaccine that would be stable at tropical temperatures. He asked if I would be interested in this problem, and suggested that freeze-drying—in which he himself was concerned as a means of preserving blood plasma—might be a useful technique.

"At the outset I aimed for a method that would yield consistent heat stability results and set myself these additional criteria: the vaccine must still comply with the official standard of potency after at least one month at 37 °C (a requirement later adopted by the British and European Pharmacopoeias and by WHO); if dried, it must be safe and easy to reconstitute in the field by vaccinators with little technical training; and it must be possible to produce it economically on a large scale. In addition, it would of course have to comply with the official regulations on bacterial contamination.

"In my field experiments I compared the stabilities of the glycerinated and lanolinated vaccines in current production; although the latter was the more stable at 22 °C, it completely lost its potency within a month at 37 °C. I then tried Otten's method of drying crude vaccine from the liquid state over sulphuric acid; vaccine made in this way was widely used in Indonesia and some batches had survived at ambient temperatures for remarkably long periods. There was however considerable batch-to-batch variation, a finding that I confirmed; furthermore, the bulk dried vaccine was cumbersome to handle and distribute into ampoules.

"Without further ado I then started to explore the possibilities of drying from the frozen state, using a large centrifugal dryer of the type that had recently been invented by R. Greaves at Cambridge. This machine was made in the Institute's workshops and although primitive in appearance, it worked very well; the main difficulty was the making of vacuum-tight seals, at that time rather more of an art than a science.

"The general plan was to prepare experimental vaccines in various ways, to freeze-dry part of the batch and then to compare the keeping properties of the dried and corresponding liquid preparations at 4 °C, 22 °C and 37 °C. Each batch was tested monthly, sometimes for more than two years. It was soon clear that dried lots of routinely-produced animal skin vaccine varied considerably in stability; materials partly purified by differential centrifugation yielded much more uniform results.

"The next problem was rather more difficult. Phenol was added to destroy contaminating bacteria; this had to be done before drying, otherwise the bacteria would have been preserved along with the virus. Although phenol in low concentration does not harm vaccinia virus in liquid suspensions, vaccines containing it lost much of their potency on freeze-drying; this was eventually traced to the tendency of phenol to come out of solution during rapid cooling and become concentrated to a degree that killed the vaccinia virus. This effect could however be prevented by adding peptone to a concentration of 5% before drying the vaccine. Fortunately, among the many additives tried, peptone also proved by far the best for preserving potency at all temperatures tested; it had the further advantages of being non-antigenic, cheap and easy to reconstitute.

"After much experimentation, a satisfactory method was devised for purifying animal vaccine and freeze-drying it after adding peptone to a concentration of 5%. Vaccine thus prepared consistently maintained its original potency for at least three months at 37 °C; in later experiments, batches stored at the high temperature of 45 °C still gave 100% successful primary vaccination after four years. The criterion for the permissible minimum content of vaccinia virus was fixed by determining the amount of virus needed to achieve 100% successful vaccinations; the final step in the development stage was the devising of a simple and safe method for reconstituting the dried vaccine in the field. It then remained only to scale up all the processes to a point at which full production could begin; this was accomplished by 1953." (L. H. Collier, personal communication, 1980.)

## Quality Control

### *At the national level*

Smallpox vaccine had been used for many years before the concept developed that it should be subject to national quality control, in addition to whatever steps the manufacturer might take to protect the reputation of his products. By the mid-1920s a few countries had developed regulations governing biological products destined for medical use, such as vaccines, toxoids and sera.

In January 1926 the Smallpox and Vaccination Commission of the Health Organisation of the League of Nations decided to collect information from vaccine producers regarding the production, testing, standardization, storage and delivery of smallpox vaccine. France, Germany, the Netherlands, Switzerland and the United Kingdom participated in this survey, which was completed in 1927. On the basis of the results, the United Kingdom incorporated standards into the Therapeutic

Substances Regulations 1927 (England and Wales, Ministry of Health, 1928a). A brief review of these regulations provides some information on how the quality control of smallpox vaccine was then being conducted in the United Kingdom. The regulations defined certain conditions concerning the qualifications of staff, the animals to be used, the housing of such animals, precautions to be observed during the production process, specifications for final containers for the use of the vaccine, and labelling. The provisions relating to the purity of the vaccine indicated that each batch should be tested to ensure the absence of anaerobic organisms and streptococci: bacterial counts should be less than 5000 per ml. Scarification of the cornea of guinea-pigs or the skin of rabbits with diluted vaccine lymph was the principal method for potency testing, typical vaccinia lesions being regarded as the criterion for adequate potency. It seems likely that the quality control of vaccine lymph was being carried out along these lines in many other

countries of Europe and perhaps in North America at that time. During this period the application of the control system depended on the interest and capabilities of the production laboratory, since there was no mechanism for independent assessment.

#### *At the international level*

In 1946 the Interim Commission of the World Health Organization was set up, taking over the functions of the Health Organisation of the League of Nations. The Commission established a section (unit) of Biological Standardization in the Secretariat. The responsibilities of this section included the establishment of international standards for biological assay, the formulation of requirements for biological products, the coordination of research on biological standardization and the encouragement of Member States to set up national control laboratories for biological substances (Outschoorn, 1973).

WHO standards for smallpox vaccine were first established in 1958, at a meeting in which 6 experts from Europe, 2 from North America, 2 from Asia, and 1 from North Africa participated (WHO Study Group on Requirements for Smallpox Vaccine, 1959). This meeting suggested the criteria that should be established for smallpox vaccine, in relation to the strain of vaccine, methods of preparation of the vaccine lymph, bacterial counts, use of the seed lot system, methods of potency assay and standards for the heat stability of freeze-dried vaccine. In 1965 these requirements were revised in the light of experience accumulated during the intervening period (WHO Expert Group on Requirements for Biological Substances, 1966). Meanwhile, after extensive collaborative studies, the first reference preparations of smallpox vaccine were established in 1962 (ampoules containing 14 mg of freeze-dried smallpox vaccine; Krag & Bentzon, 1963) and of anti-smallpox serum in 1965 (ampoules containing 84.3 mg of freeze-dried pooled human serum—1000 IU per ampoule; WHO Expert Committee on Biological Standardization, 1967). These reference preparations were produced with a view to facilitating the laboratory investigations needed in order to improve vaccine quality. The modifications proposed in 1965 reflect the progressive improvement in vaccine production and assay.

*Seed lot system.* In the 1959 WHO requirements, up to 10 serial passages of the seed virus were permitted. Meanwhile, advances in viral genetics and practical experience with poliovirus vaccine had drawn attention to the need to minimize the serial passage of seed virus if genetic stability was to be maintained. In response to this new knowledge, the acceptable maximum number of passages of vaccinia virus secondary seed lots was reduced to 5.

*Bacterial count.* In 1959 the acceptable count was set at less than 1000 non-pathogenic bacteria per ml, whereas in 1965 this number was reduced to less than 500 per ml, because manufacturers had improved their techniques for the handling of animals and the collection of the vaccine pulp.

*Potency.* Cockburn et al. (1957) found that vaccine with a titre of  $1.5 \times 10^7$  pock-forming units per ml gave 100% successful takes in groups of about 100 primary vaccinees, and in a more elaborate statistical analysis of their data (published as an annex to the article cited), C. C. Spicer showed that vaccines with a potency of  $10^8$  pock-forming units per ml should give less than 1 failure in 1000 primary vaccinations. In 1959 a titre of  $5 \times 10^7$  pock-forming units had been recommended as the minimal acceptable potency, but in 1965 the level was doubled, to  $10^8$  pock-forming units per ml. This change was based on observations made by the WHO Expert Committee on Smallpox (1964), to the effect that:

"...vaccines of relatively poor potency are adequate for successful primary vaccination but inadequate for successful revaccination. Their use for revaccination gives a false sense of security, since a negative response is often taken as evidence of immunity. Failure in successful revaccination explains in part the continued presence of smallpox in some endemic countries where vaccination is regularly practised."

Changes were also made in the recommended method of titration. Following the observations by Cockburn et al. (1957) that pock counting was considerably more precise than rabbit scarification (see Table 7.1) and that pock counts correlated well with take rates (Fig. 7.1), the 1959 recommendation that rabbit-skin scarification and pock counting were acceptable alternatives was changed so as to eliminate scarification.

*Heat stability.* The requirements for heat stability remained unchanged; vaccine

should maintain the minimum acceptable potency (now  $10^8$  pock-forming units per ml) after incubation at 37 °C for 4 weeks.

*Implementation of the WHO recommendations.* The WHO requirements for smallpox vaccine established in 1965 remained in effect throughout the Intensified Smallpox Eradication Programme. However, the promulgation of standards by WHO in 1959, and again in 1965, and their application in laboratories in diverse countries were very different matters, especially before the WHO Smallpox Eradication unit organized an international quality control system in 1968. Before that, many laboratories lacked competent staff, adequate facilities and interest. Some production laboratories did no potency assays at all; others relied on tests in unvaccinated children, regarding 9 takes out of 10 as satisfactory (a result that could be obtained with a vaccine whose titre was as low as  $10^{6.5}$  pock-forming units per ml; see Fig. 7.1). For producers who did wish to titrate their production lots, reference preparations of known titre were required. However, only 2 or 3 ampoules of the international reference vaccine, prepared in 1962, were supplied to production laboratories, from which the laboratories were expected to produce their own working standards. In developed countries this was no problem, but it was beyond the

capacity of many laboratories in developing countries. Further, some developed countries did not adopt the standards recommended by WHO. For instance, in the USA, the rabbit-skin scarification method was still used as the method for estimating the potency of smallpox vaccine until 1971. In Japan, a titre of  $5 \times 10^7$  pock-forming units per ml remained the officially accepted minimum level of potency for several years after 1965. National quality control of smallpox vaccines was exercised in only a few countries.

From 1959 to 1966, WHO's participation in monitoring the quality of vaccine was limited to material which had been donated to the Organization for use in the global eradication programme. This amounted to only about 7 million doses a year (total over the period: some 46 million doses; see Chapter 11, Table 11.1). Material supplied through bilateral assistance or by local production was not tested by WHO. This often resulted in the use of substandard vaccine. As A. S. Ootschoorn, former Chief Medical Officer of the WHO Biological Standardization unit, said:

"It has never been feasible for W.H.O. laboratories to be established which would undertake control of biological products on behalf of Member States. There would perhaps be a place in the future for private enterprise to make available sources of expertise or advisory services and even testing facilities from which Member Governments could call for assistance outside of the World Health Organization." (Ootschoorn, 1973.)

The absence of effective quality control was one of the first obstacles that had to be overcome when the Intensified Smallpox Eradication Programme was established in 1967 (see Chapter 11).

Fig. 7.1. Relationship between pock counts of vaccinia virus and the percentage of successful takes on primary vaccination. The solid line represents a theoretical curve based on probit analysis assuming a 50% probability of a take at a dose of  $3 \times 10^5$  pock-forming units per ml. (From Cockburn et al., 1957.)

## VACCINATION TECHNIQUES BEFORE 1967

During the long history of vaccination, practices and techniques were gradually developed that differed from country to country. However, by the 1950s they shared many features, which are summarized below.

### Vaccination Site

The most commonly used site for primary vaccination and revaccination was on the

### "Vaccination" and "Immunization"

The term "vaccination" sometimes causes confusion because it has both a specific and a general meaning. Vaccination against smallpox was the only form of preventive immunization against an infectious disease until 1880, when Pasteur developed techniques of attenuation of virulence and protective inoculation of animals against anthrax and chicken cholera. In 1881, in order to recognize Jenner's contribution to the concept of inoculation with attenuated microbes as a method of protection against infectious diseases, Pasteur proposed that this procedure should be called "vaccination" and the product used a "vaccine", whatever its nature. This terminology remains in use, though the general procedure is now usually called "immunization"; the product is still called a vaccine—e.g., poliovaccine, measles vaccine. In this book "vaccine" always means smallpox vaccine unless specified in some other way.

extensor surface of the upper arm, over the deltoid muscle. In some parts of India, however, revaccination was carried out on the flexor surface of the forearm.

The skin site was usually rubbed with alcohol or acetone. Although studies described in Chapter 11 showed that such skin preparation was unnecessary and could, if the alcohol did not completely evaporate, partially inactivate the vaccine, the practice continued to prevail in many countries.

### Methods of Vaccination

Several methods were used, all involving the introduction of the virus into the Malpighian layer of the epidermis, with a variety of instruments (Plate 7.5). In most countries, either the skin was scarified by a single linear incision or scratch, or vaccine was introduced into the epidermis by the multiple pressure method, but in a few places a rotary lancet was used.

#### *Dermal scarification*

A scratch about 5 mm long was made in the skin with a needle, a lancet or a small knife and the vaccine suspension was rubbed into the site. A single cut or cross cuts were made, in 1, 2 or 4 different sites. This was essentially the same method as had been used for variolation in Europe during the latter part of the 18th century.

#### *Multiple pressure method*

From very early times attempts were made to deposit virus between the skin layers by

methods other than the scratch method or intradermal inoculation with a syringe and needle. Leake (1927), in a pamphlet offering official advice on vaccination to physicians in the USA, recommended the "multiple pressure" method (Fig. 7.2), which was subsequently adopted in several other countries (Parish, 1944; England and Wales, Ministry of Health, 1956). A small drop of vaccine was placed on the skin and the side of a straight surgical needle, held tangentially to the skin surface, was pressed firmly and rapidly into the drop by an up-and-down motion, about 10 times for primary vaccination and 30 times for revaccination. Excess vaccine was wiped off. Only 1 insertion site was recommended, for both primary vaccination and revaccination. This method was less traumatic than scarification, while still producing an adequate take. However, it was difficult to train vaccinators to exert sufficient pressure, and this sometimes caused unsuccessful vaccinations.

#### *Rotary lancet*

Vaccination using the rotary lancet (Plate 7.5) was carried out in many parts of the Indian subcontinent. A rotary lancet designed for vaccination was first described by Rose (1871) and was manufactured in the United Kingdom and later in India. The vaccine was placed on the skin with the small spoon on one end of the instrument. The disc, anchored by the slightly longer central spike, was rotated in such a way that the small lateral spikes abraded the epidermis. If potent vaccine was used, the ensuing trauma produced a large and severe vaccinal reaction, which was a frequent cause of refusal to undergo vaccina-

**Plate 7.5.** Instruments used for vaccination (actual size) before the introduction of the bifurcated needle. **A:** Rotary lancet. **B:** Vaccinostyle, used for scratch vaccination. **C:** Straight surgical needle, used for vaccination by scratch or multiple pressure method (See Fig. 7.2).

tion. Further, the vaccines then in use were often heavily contaminated with bacteria and the use of the rotary lancet could produce scarring even when the infection had been due to pyogenic bacteria rather than vaccinia virus. Failures sometimes occurred when vaccinators did not allow the lancet to cool adequately after the flaming that was carried out after each vaccination.

Although the WHO Expert Committee on Smallpox (1964) recommended that this method should not be used, it was still routinely employed in some parts of the Indian subcontinent long after this. During the smallpox eradication programmes in Pakistan and India (see Chapters 14 and 15), the programme staff hunted for rotary lancets and confiscated a large number of them from vaccinators who were reluctant to abandon the method but were thus obliged to use the bifurcated needle. However, many remained

in use, particularly in the municipal corporations in India, as late as 1974.

### Age for Primary Vaccination

Throughout the 19th century, stress was placed on the primary vaccination of infants as the optimum method of providing protection against smallpox, and laws for compulsory vaccination during the first 3-6 months of life were introduced in many countries. However, in the St Petersburg Foundling Hospital, infants aged 7-8 days were vaccinated with lymph maintained by arm-to-arm vaccination from 1801, when the Empress of Russia obtained lymph from Jenner, until 1867, when vaccine from cows began to be used. There were no serious complications, but a few infants required repeated inoculation before a take was obtained. Compulsory registration made it possible to keep track of foundlings until they were 25 years old, so that observations on the efficacy of vaccination were possible. There were 17 epidemics of smallpox in St Petersburg between 1826 and 1846; out of about 15 000 foundlings, only 34 had smallpox, with only 1 fatality (Fröbelius, 1869; Donnally & Nicholson, 1934). Elsewhere, the vaccination of newborn infants exposed to cases of smallpox was occasionally recommended, but routine vaccination of newborn children in a hospital appears to date from the early 20th century, in some centres in France and Germany. The compulsory vaccination of

**Fig. 7.2.** The principle of the multiple pressure method of vaccination. Virus on the tip of the needle is deposited within the deeper layers of the epidermis.

**Plate 7.6.** Lesions in a Pakistani child due to use of the rotary lancet, with insertions at 4 separate sites.

neonates was first practised in Detroit, USA, at the time of an epidemic of variola major in 1925 (Lieberman 1927).

Espmark & Rabo (1965a,b) examined the effect of maternal antibody on the response of infants vaccinated under the age of 1 month. They found that more potent vaccines were needed for these younger infants than for infants vaccinated at 5–12 months of age, but that with potent vaccines ( $10^{8.0}$  TCID<sub>50</sub> per ml or higher) take rates and neutralizing antibody responses were equally good in both groups, and the local signs and constitutional symptoms were milder in the younger infants.

In most countries of Europe and North America, infants were vaccinated during the second 6 months after birth. In the United Kingdom (Conybeare, 1964b) and in the USA (Neff et al., 1967; Lane et al., 1969), investigations into the complications of vaccination indicated that the risk of postvaccinial encephalitis in infants vaccinated before the age of 1 year was greater than that in those

vaccinated later. This led to recommendations that vaccination should be postponed until the 2nd year of life. However, in countries in which the maternal antibody level was reasonably high e.g., Sweden it was shown that vaccination in the first 3 months of life was effective, and was usually attended by less severe signs than vaccination later in infancy (Espmark et al., 1973).

Other considerations were important in endemic countries, in which the case-fatality rate for smallpox was very high in young infants. Noting that in Madras, India, most infants were born in hospitals and were accessible as neonates but often difficult to trace after they left hospital, Rao carried out a pilot study in 1959–1960 in which 2500 infants were vaccinated with liquid vaccine on the 3rd day of life, with a take rate of 82% (Rao & Balakrishnan, 1963). Subsequently, take rates of 100% were obtained with freeze-dried vaccine, and the practice of neonatal vaccination was extended to a number of urban areas throughout India (WHO/SE/71.30, Rao).

### Interpretation of the Results of Vaccination

In susceptible individuals, smallpox vaccination produced a typical Jennerian pustule at the inoculation site and frequently swelling and tenderness of the draining lymph node. At the height of the reaction there was usually slight fever and the subject might feel indisposed for a few days. A feature of smallpox vaccine, which among the variety of agents now used for immunization against infectious diseases is shared only with BCG vaccine, is that successful vaccination produced a characteristic skin reaction which could be readily observed and which usually left a permanent and characteristic scar. This had both immediate and long-term consequences. Observation of the nature of the cutaneous lesion after recent vaccination or revaccination enabled the vaccinator to decide whether the virus had replicated and the patient had thus been rendered immune to smallpox. In the longer term, the vaccination status of an individual or a population could be determined, with considerable accuracy, by visual examination for vaccination scars, thus obviating the need for a serological survey. For these reasons, special attention was devoted to skin reactions after both primary vaccination and revaccination.

The clinical features of smallpox in unvaccinated and vaccinated persons and the pathogenesis and immune responses in smallpox and after vaccination are described in Chapter 1 and Chapter 3 respectively. It may be useful to recall here the salient features of immunity to smallpox (see box).

#### *Major reaction in primary vaccination*

A typical Jennerian pustule was termed a "major reaction", and constituted evidence that the vaccinee would be protected against smallpox. The course of the reaction is illustrated in Plate 7.7A and C. A papule appeared at the vaccination site on the 3rd day after vaccination, and within 2 or 3 days this became vesicular, to constitute the umbilicated and loculated "Jennerian vesicle". As in smallpox (see Chapter 1), the vesicle soon became pustular, owing mainly to the entry of polymorphonuclear cells, the migration of which was stimulated by the viral infection itself, and the surrounding area became erythematous and indurated to a much greater extent than was found in the skin lesions of

smallpox. The area of erythema reached a maximum between the 8th and 12th days (usually on the 9th or 10th day), and at this time the draining lymph nodes were enlarged and tender and the subject often sustained a mild fever and may have felt unwell. The pustule dried from the centre outwards to become a dry brown or black scab which fell off about 3 weeks after vaccination, to leave a typical pitted scar.

For routine inspection, observation of the pustule on the 7th day confirmed whether vaccination had been successful. The reaction to vaccinia virus could be readily distinguished from reactions due to bacterial infection, both by its time course and its characteristic appearance.

#### *Revaccination*

As described in Chapter 3, successful primary vaccination elicited not only humoral immunity, but also a longer-lasting cell-mediated immunity, which conditioned the response to revaccination. Interpretation of the results of revaccination was sometimes

### **How Vaccination Protected against Smallpox**

A large part of the DNA of all orthopoxviruses is very similar and codes for polypeptides that have a close resemblance in all orthopoxviruses. Vaccination against smallpox consisted in the production of an infection of the skin with vaccinia virus, with extension to the lymph nodes and spleen, organs concerned with the immune response. Because vaccination involved infection of the skin with a relatively large dose of a virus that replicated rapidly, generalization of infection and therefore the immune response occurred more quickly than they did in naturally acquired smallpox. This explains why vaccination during the incubation period of smallpox sometimes aborted or modified the clinical course of the disease.

The immune response to vaccination results in the development of cell-mediated immunity, probably to antigens expressed on the surfaces of infected cells, and a number of humoral antibodies, some of which can neutralize infectivity and may persist for long periods. There are also memory cells for both cell-mediated and humoral immune responses, which wane slowly.

For a few years after vaccination the level of immunity may have been sufficient to prevent completely the replication of variola virus. A somewhat lower level of immunity may have allowed limited replication of variola virus, short of symptom production, but with an anamnestic immune response (subclinical infection). Still lower levels of immunity may have allowed the generalization of variola virus to occur, but stimulation of the memory cells would have produced an accelerated immune response which would have modified the clinical manifestations of smallpox (modified-type smallpox). After many years the immunity provided by vaccination might have waned to such an extent that the attack of smallpox might not have been modified in any way and might indeed have been fatal.

difficult, in terms of evaluating their significance in relation to protection against smallpox. Sometimes there was no reaction at all, a result which was usually due to the use of vaccine of low potency, and which was impossible to interpret correctly (WHO Expert Committee on Smallpox, 1964). If it did occur, the reaction to revaccination could be maximal at any time between the 2nd and the 8th day. During the period before the global smallpox eradication programme, 3 varieties of response used to be distinguished (see, for example, van Rooyen & Rhodes, 1948):

(1) *Immediate reaction.* Although it used to be described as an "immediate" reaction, dermal hypersensitivity to vaccinia protein produced erythema during the first 24-48 hours after vaccination. It was a classical delayed hypersensitivity reaction, which could be elicited by non-infectious vaccine as well as by active vaccinia virus. Such a response might be given by highly immune individuals even when potent vaccine was used, but it could also occur in individuals with little or no residual immunity who were given inactive vaccine.

(2) *Accelerated reaction.* Persons with some residual cell-mediated immunity but not enough to inhibit viral replication experienced erythema and the development of a vesicle and sometimes a pustule, which evolved in a sequence more rapid than that seen in a primary vaccination reaction (Plate 7.7B and D). Those with substantial immunity experienced little more than an immediate reaction, whereas those with minimal residual immunity experienced a reaction almost indistinguishable from that seen after primary vaccination. The result of revaccination was dependent on the balance between the potency of the vaccine and residual immunity. A highly potent vaccine could provoke a major reaction, perhaps slightly accelerated, in an individual who had failed to respond to a less potent vaccine; revaccination on the flexor surface of the forearm was more often followed by a substantial reaction than revaccination over the deltoid muscle.

(3) *Major reaction in revaccination.* If a long period had elapsed after a primary vaccination, revaccination could produce a reaction similar to that described for a primary vaccination. This was called a major reaction.

The WHO Expert Committee on Smallpox (1964) considered that the traditional classification of the reaction to revaccination as

"immediate", "accelerated" or "major", as just described, could be misleading, in terms of judging whether an individual might be susceptible to smallpox. The Expert Committee therefore recommended that revaccination should be recorded as successful if, on examination 6-8 days later, there was a pustular lesion or an area of definite induration or congestion surrounding a central lesion, which might be a scab or an ulcer. Such a response was termed a "major reaction". All others were termed "equivocal reactions"—i.e., the persons concerned could not be presumed to be immune to smallpox and were revaccinated.

## COMPLICATIONS OF VACCINATION

Smallpox was such a dire disease and the effects of vaccination by comparison so trivial that for a hundred years after vaccination was introduced little account was taken of its complications in places in which smallpox was still endemic. There was a strong anti-vaccinationist movement in several countries, but this was based less on concern about the risks of the procedure than on moral and philosophical objections to compulsory vaccination (see Chapter 6). Among those who supported vaccination there was a reluctance to admit that there were any risks. For example, in the United Kingdom during the first quarter of this century, 103 deaths among 4 275 109 primary vaccinations were recorded as being "associated with vaccination", but the official view was that these "may merely indicate that the child has been vaccinated before death and that death is really attributable to some current illness" (England and Wales, Ministry of Health, 1924). However, smallpox vaccination consisted in the infection of the human host with a virus that must replicate and produce lesions if it was to evoke immunity. Any such procedure that is used on a sufficiently large scale will be associated with occasional cases in which more severe lesions result. The pustular skin lesion illustrated in Plate 7.7 and the fever and lymphadenitis described earlier were the normal results of infection with vaccinia virus. Vaccination was sometimes complicated by much more severe symptoms and was sometimes fatal. These severe complications became a matter of much concern in many industrialized countries, in which endemic smallpox had been eliminated but routine vaccination

programmes were maintained in order to protect the community in the event of the importation of smallpox from an endemic area.

### Types of Complication

Three groups of complications occurred among vaccinated subjects: abnormal skin eruptions, disorders affecting the central nervous system, and a variety of other rare or less severe complications.

#### *Abnormal skin eruptions*

Three kinds of abnormal skin eruption were recognized. Two of them, eczema vaccinatum and progressive vaccinia, were associated with abnormal host reactions; true generalized vaccinia occurred in otherwise healthy persons.

*Eczema vaccinatum.* This complication occurred in vaccinated persons or unvaccinated contacts who were suffering from or had a history of eczema. Either concurrently with or shortly after the development of the local vaccinal lesion (or after an incubation period of about 5 days in unvaccinated eczematous contacts) a vaccinal eruption occurred at sites on the body that were at the time eczematous or had previously been so. These areas became intensely inflamed, and sometimes the eruption later spread to healthy skin. Constitutional symptoms were severe, with high temperature and generalized lymphadenopathy, and the prognosis was grave in infants in whom large areas of skin were affected (Plate 7.8A).

It was to allow the safe vaccination of children with eczema that Kempe (1968) promoted the use of the CVI-78 attenuated vaccine (see Chapter 11), and vaccinia-immune globulin was often used to treat these cases, in both vaccinated persons and those accidentally infected. The risk of this infection remains, since military personnel continue to be vaccinated in some countries. Several cases of vaccinal infection (and thus potentially of eczema vaccinatum) in contacts of recently vaccinated military personnel were reported in Canada and the United Kingdom, and in the USA as recently as 1985 (*Journal of the American Medical Association*, 1985).

*Progressive vaccinia (vaccinia necrosum).* This complication occurred only in persons who suffered from a deficient immune mechanism,

1964

such as agammaglobulinaemia, defective cell-mediated immunity or immunodeficiency associated with tumours of the reticulo-endothelial system or the use of immunosuppressive drugs (see Chapter 3, Fig. 3.8). In these cases the local lesion at the vaccination site failed to heal (Plate 7.8B), secondary lesions sometimes appeared elsewhere on the body and all lesions spread progressively until—as was likely—the patient died, usually 2–5 months later.

*Generalized vaccinia.* As mentioned earlier, vaccinia virus produced a systemic infection in man, with transient viraemia. Very rarely a generalized vaccinal rash, sometimes covering the whole body, occurred 6–9 days after vaccination (Plate 7.8C). The course of the individual skin lesions resembled that of the lesion at the vaccination site, but if the rash was profuse the lesions sometimes varied greatly in size. The generalized eruption usually did not have the “centrifugal” distribution which was characteristic of the rash of smallpox (see Chapter 1). Generalized vaccinia was not associated with severe immunodeficiency, and the prognosis was good.

*Accidental infection.* This was the most common complication of vaccination, but it was usually not serious and was certainly greatly

underreported. The commonest sites, in cases that were seen by physicians, were the eyelids (Plate 7.8D), vulva and perineum. Two categories were included in a national survey carried out in the USA (see below and Table 7.3): accidental infection of secondary sites on vaccinees and accidental infection of normal contacts of vaccinated persons.

#### *Postvaccinial tonsillitis*

Some Soviet authors (Braginskaya et al., 1971; Gurvich et al., 1974) regard postvaccinial tonsillitis as a not uncommon complication of primary vaccination. Gurvich et al. (1979) reported the recovery of vaccinia virus from pharyngeal swabs in 49% of children with postvaccinial tonsillitis, compared with 7% of those with no complications.

#### *Postvaccinial encephalitis*

This was the most serious complication of vaccination in persons in whom there was no contraindication for the procedure. There is an extensive literature on the subject, reviewed by Wilson (1967); the histopathology is described in Chapter 3. One difficulty in assessing postvaccinial encephalitis is that the term encompassed 3 conditions, only 2 of which were due to vaccinia infection (see box).

*Concomitant disease.* A temporal association does not prove causation, and some cases of encephalitis after vaccination were undoubtedly merely coincident disease due to other

causes. For example, Greenberg & Appelbaum (1948) noted that of 49 cases diagnosed ante mortem as postvaccinial encephalitis, 4 out of the 8 fatal cases proved on autopsy to have been due to other causes (2 cases of tuberculous meningitis, 1 brain tumour and 1 case of hypertensive vascular disease). Some of the non-fatal cases may also have been coincidental.

Cases of encephalitis may be expected to occur in any large population of children within a defined period even if no vaccines of any kind are administered. A survey in New Jersey, USA, in 1965 showed that in the absence of vaccination 2.86 cases of encephalitis occurred per million children 1-9 years old per 28-day period; an investigation in Florida in 1968 reported a figure of 2.28 cases per million, in the same age group and during the same time span (Landrigan & Witte, 1973). Figures of a like magnitude were found in the National Childhood Encephalopathy Study in the United Kingdom, undertaken in 1976 because of widespread public and professional concern over the safety of pertussis immunization (England and Wales, Department of Health and Social Security, 1981). The results showed that the majority of the severe neurological disorders studied were not associated with recent immunization (within 28 days) and must be attributed to other causes. Nevertheless, serious neurological complications were sometimes caused by smallpox vaccination, 2 forms being recognized.

*Encephalopathy and encephalitis.* The pathological distinction made by Vries (1960)

### **Central Nervous System Disease after Vaccination**

"Postvaccinial encephalitis" probably includes several different pathological conditions, of which 3 are specific. First, in any procedure practised as widely as was vaccination against smallpox, there were inevitably some cases of the temporal coincidence of vaccination and some other quite unrelated disease that produced signs of encephalitis. Very rarely, there could be infection of the meninges with vaccinia virus. In infants under 2 years of age there was sometimes a general hyperaemia of the brain, mild lymphocytic infiltration of the meninges, widespread degenerative changes in ganglion cells and occasionally perivascular haemorrhages—what Vries (1960) called postvaccinial encephalopathy. The commonest form, in individuals over 2 years of age, was characterized by perivenous demyelination and microglial proliferation in the demyelinated area, with some lymphocytic infiltration but very little oedema. The pathological features of this form, for which the term "postvaccinial encephalitis" (or "encephalomyelitis") was usually reserved, were similar to those seen in other post-infection encephalitides.

between encephalopathy, in infants under 2 years of age, and postvaccinal encephalitis or encephalomyelitis, with characteristic perivenous demyelination, in individuals over 2 years of age, is important and can be tentatively recognized by consideration of the age of the subject, the symptomatology and the incubation period. According to Spillane & Wells (1964) the onset in cases of encephalopathy was often violent, characterized by convulsions; hemiplegia and aphasia were common, the period of amnesia was short, and the spinal fluid, though under increased pressure, was often normal. Recovery was frequently incomplete, the patient being left with cerebral impairment and hemiplegia.

On the other hand, in the perivenous demyelinating microglial encephalitis following vaccination in subjects over 2 years of age the onset was usually abrupt, with fever, vomiting, headache, malaise, and anorexia, succeeded by such symptoms as loss of consciousness, amnesia, confusion, disorientation, restlessness and delirium, drowsiness, convulsions and coma, with incontinence or retention of urine, obstinate constipation, and sometimes meningismus. Paralysis, when it occurred, tended to be of the upper neuron type. The spinal fluid showed an increase in the concentration of protein and the number of lymphocytes. The case-fatality rate was usually about 35% and in fatal cases death usually occurred within a week. In patients who survived, recovery often set in within a few days and was complete within 2 weeks.

Weber & Lange (1961) found that almost all cases of postvaccinal central nervous system disease in children less than 2 years old and diagnosed as encephalopathy had incubation periods of 6-10 days (mean,  $8.6 \pm 2.3$  days) from the date of vaccination (Table 7.2). By contrast, 96% of 161 cases of postvaccinal encephalitis were in individuals over 2 years of age and most had incubation periods of 11-15 days (mean,  $12.3 \pm 2.1$  days), an interval compatible with an immunopathological basis for the syndrome. In fatal cases, the day of death in infantile encephalopathy was on average  $10.5 \pm 3.0$  days after vaccination; the corresponding figure for encephalitis was  $16.3 \pm 3.9$  days.

Postvaccinal encephalitis began to cause concern in the 1920s and 1930s (Hurst, 1953), when it appeared to be especially frequent in several European countries. As smallpox became less common, the importance of this serious complication of vaccination increased,

mainly because there was no way of assessing the risk of postvaccinal encephalitis beforehand—unlike progressive vaccinia and eczema vaccinatum, for which there were known predisposing conditions. No means were known then, or in fact are known now, of predicting the occurrence of post-infection encephalitis, whether attributable to measles, vaccination against rabies, or smallpox vaccination (Johnson, 1982).

#### *Other complications of vaccination*

Very rarely, the fetus carried by a woman who had been vaccinated was infected *in utero*. Although a possible example of this was described by Jenner (1809), up to 1978 only 28 cases had been reported in the scientific literature, almost all as single case reports (A. Gromyko, personal communication, 1978). Of the 25 cases for which data are available, 21 occurred in mothers who had been vaccinated during the first 6 months of pregnancy and 4 occurred in mothers vaccinated later. In the first group, a fetus with generalized vaccinia was delivered on average 8 weeks after the vaccination, and in the second group about 4 weeks after vaccination. Many cases were fatal, the fetus being stillborn or dying a few days after birth. There is no convincing

<sup>a</sup> Based on Weber & Lange (1961).

evidence that congenital malformations ever resulted from vaccination of the mother; the infected fetus usually died, but if it survived it recovered completely (Töndury & Foukas, 1964). The mother usually sustained a normal vaccination reaction; the occurrence of fetal vaccinia was additional evidence that viraemia occurred during normal vaccination.

Until smallpox was eradicated, smallpox vaccination was the most widespread immunization procedure in the world. It was thus inevitable that there should sometimes be a temporal coincidence between vaccination and the onset of certain other rare conditions of unknown etiology, such as multiple sclerosis. One rare association that probably had some etiological significance was the occurrence of a malignant skin tumour, such as melanoma, in the smallpox vaccination scar, usually many years after vaccination (Marmelzat, 1968). Vaccinal osteomyelitis was occasionally reported, the diagnosis of which was sometimes confirmed by the recovery of vaccinia virus (Sewall, 1949).

Sometimes vaccines were contaminated with pyogenic cocci, or the introduction of staphylococci into the skin during the vaccination led to localized bacterial infection.

### Frequency of Complications

Apart from a multitude of case reports, estimates of the frequency of severe complications—especially postvaccinal encephalitis, which was widely recognized in the 1930s—were produced in many European countries during the period 1940–1965. These have been summarized by Wilson (1967). More useful, because they are more comprehensive, are the two surveys carried out in the USA (nation-wide and in 10 states) by the Communicable Disease Center (CDC—subsequently renamed the Centers for Disease Control), Atlanta, Georgia. Using different methodologies, these surveys were designed to estimate the incidence of all complications of smallpox vaccination in the USA for the year 1968. The methodologies of these two surveys will be described before the frequency of various complications is discussed.

#### *Methodology of the CDC surveys*

Following a nation-wide retrospective survey of complications occurring during the

year 1963 (Neff et al., 1967), CDC undertook a comprehensive prospective national survey, and a confirmatory, less extensive, survey through physicians in 10 selected states, of the frequency of complications of smallpox vaccination in the USA in the year 1968.

*National survey (Lane et al., 1969).* Efforts were made to identify all possible complications, on a national scale, using 8 methods to obtain information.

(1) The American Red Cross Vaccinia-Immune Globulin (VIG) distribution system supplied the names of physicians who had been provided with VIG, which was in short supply, for patients. It was distributed from some 10 centres and released to the attending physician only after a telephone conversation with the physician at the Red Cross centre and due justification of its use had been made. The attending physicians were asked for clinical and epidemiological information on their patients shortly after receiving VIG.

(2) Consultants to the Red Cross VIG Program supplied the names of patients suspected of having complications of vaccination who came to their attention but did not receive VIG.

(3) The National Encephalitis Surveillance Program of CDC received reports from each state of all cases of encephalitis, no matter what the cause.

(4) Death certificates citing complications of vaccination were scrutinized.

(5) Casual reports reaching state and territorial epidemiologists regarding vaccination complications that had not been officially reported were transmitted to CDC.

(6) The Burroughs Wellcome Company supplied information on patients who received the drug metisazone (Marboran) for the treatment of complications of vaccination.

(7) Reports were provided by smallpox vaccine producers who had received complaints from patients with complications allegedly attributable to their products.

(8) The Viral Exanthems Unit of CDC reported on specimens submitted to its diagnostic laboratory for the confirmation of vaccinia virus.

The results obtained in this national survey, expressed in absolute numbers and as cases per million vaccinations, are set out in Tables 7.3 and 7.4 respectively.

*Ten-state survey (Lane et al., 1970b).* Ten states, whose populations constituted 11.6%

of the total population of the USA, were chosen, and information was sought there through mail surveys directed to practising physicians. The states in question were selected partly because of their size (not too large) and partly because of the interest shown by their state epidemiologists and the presence of epidemic intelligence service officers assigned by CDC. Some 84% of physicians responded in 8 of the states and 44% and 49% respectively in the other 2. The questionnaires sought information on any patients with complications of vaccination.

The physicians' diagnoses were accepted for minor complications, but clinical data for more severe complications were thoroughly reviewed and accepted only if the information was considered adequate. The results of this survey are presented in Tables 7.5 and 7.6.

#### *Comparisons of data from different sources*

Lack of generally accepted diagnostic criteria, within countries and between countries, as well as variability in the completeness of reporting, makes it difficult to arrive at comparative judgements. Problems of various kinds were associated with each of the important complications. For example, some physicians reported patients who had erythema multiforme accompanying vaccination, or even accidental infection of a site or sites elsewhere on the body, as "generalized vaccinia". Others restricted this term to cases with a generalized rash (Plate 7.8C).

Most important, there were no generally accepted criteria for the diagnosis of postvaccinial encephalitis. In some countries all reports of postvaccinial encephalitis were reviewed by an experienced team; in others the report was based on the views of the attending physician, who might report as encephalitis cases in which convulsions or some other single symptom occurred, or cases with high fever and drowsiness after vaccination. In addition, there were always a few cases of encephalitis due to other causes which were merely coincident with vaccination, a problem that was dealt with in some countries by national encephalitis surveys.

As regards the USA in 1968, significantly more cases of all types of complication were found in the 10-state survey than in the national survey (compare Tables 7.4 and 7.6). This presumably resulted from the more intensive effort to discover all cases of compli-

cations made possible by the methodology of the 10-state survey, the data from which provide the better basis for comparison of complication rates in the USA with those in other countries.

*Eczema vaccinatum.* The CDC national survey recorded 58 cases of eczema vaccinatum among primary vaccinees, 8 among persons who had undergone revaccination and 60, with 1 death, among persons infected by contact. The frequencies were over 3 times higher than this in the 10-state survey (38.5 compared with 10.4 per million after primary vaccination and 3.0 compared with 0.9 per million after revaccination).

Apart from the CDC survey, few data on the frequency of this complication are available. In the mass vaccination campaign that followed the importation of smallpox into New York in 1947, during which 5-6 million people were vaccinated (but childhood eczema was accepted as a contraindication to vaccination), 10 cases of eczema vaccinatum occurred among vaccinees and 28 cases among persons who had not been vaccinated but had been in intimate contact with a recently vaccinated subject (Greenberg, 1948). There was an outbreak of smallpox in South Wales in 1962-1963 and about 900 000 persons were vaccinated. Waddington et al. (1964), who probably saw all patients with severe skin eruptions, recorded 35 cases of eczema vaccinatum (10 in vaccinees, 25 in unvaccinated contacts), with 2 deaths. The authors emphasized that the severity of eczema vaccinatum was independent of the activity of the underlying eczema, which in most patients was quiescent at the time of infection. This suggests that the virus often reached the skin by the haematogenous route, rather than as a result of the direct infection of eczematous lesions.

*Progressive vaccinia (vaccinia necrosum).* Eleven cases of progressive vaccinia were recorded in the CDC national survey. Four of these—all of whom had received vaccinia-immune globulin—were also identified in the 10-state study. In the national survey 6 cases were seen in revaccinated individuals, all of whom showed evidence of serious pre-existing illness, including leukaemia, Hodgkin's disease and lymphoma. Only 1 case occurred in a child, a 22-month-old infant with a congenital immune disorder—Bruton's hypogammaglobulinaemia. There were 4 deaths, despite treatment with vaccinia-immune globulin and metisazone.

the national survey in the USA (241.5 per million primary vaccinations compared with 23.4 per million among the same group in the national survey). Generalized vaccinia was rare in persons undergoing revaccination.

Conybeare (1964a) recorded 162 cases in about 5 million vaccinations and revaccinations carried out in England and Wales in 1951-1960. The lesion at the vaccination site matured normally, but 9-14 days after vac-

cination papular lesions appeared elsewhere on the body; these became vesicular and then pustular before scabbing. On any individual patient the lesions usually varied considerably in size. One hundred and fifty cases occurred in primary vaccinees and 106 in infants less than 1 year old. The accompanying constitutional disturbance was mild.

*Accidental infection.* Not surprisingly, many cases of accidental infection were not re-

ported and therefore did not figure in the CDC national survey. The rates in the 10-state survey were about 20 times higher (25.4 per million primary vaccinations in the national survey; 529.2 per million in the 10-state survey). Very few cases occurred after revaccination.

A special kind of accidental infection on which some statistics were collected was that associated with ocular lesions (Plate 7.8D). Sedan et al. (1953) recorded 19 cases among 850 000 vaccinees in Marseilles in 1952 (22.3 per million), and Waddington et al. (1964) noted 11 cases of vaccinia on the eyelid among 900 000 vaccinees in South Wales in 1962. The most comprehensive report (Ruben & Lane, 1970), derived from cases detected by the perusal of requests for vaccinia-immune globulin addressed to the American Red Cross, records 348 cases, most of which came to light in the years 1963 and 1968, when special national surveys had been conducted. There were also some cases that occurred in 1964, 1965 and 1969. Corneal involvement occurred in 22 cases and produced a much higher rate of residual ocular defect (Table 7.7).

*Postvaccinial encephalitis.* Although comparisons of data were difficult because of the variability of the criteria for making the diagnosis and the extent of reporting, the frequency of postvaccinial encephalitis varied greatly in different countries. Table 7.8 presents data from 5 countries (9 series of studies) which illustrate dramatically the large differences reported, especially for postvaccinial encephalitis after the primary vaccination of individuals over 2 years of age. All the statistics presented probably include a few cases of encephalitis that were merely coincident with, rather than caused by, vaccination, but the differences in frequencies are so great that they could not have been due solely to diagnostic or statistical eccentricities.

Postvaccinial encephalitis was much more common in European countries than in the USA, and more common in the countries of continental Europe than in the United Kingdom. There were also differences in the age incidence. In most countries postvaccinial encephalitis was considered mainly a risk of primary vaccination in adolescents or young adults, but in the USA the higher incidence of encephalopathy in infants under the age of 1 year led to a recommendation that compulsory vaccination should be postponed until the 2nd year of life. More detailed

analysis of the data used in Table 7.8 for various age groups showed that the frequency of postvaccinial encephalitis was greatest in the age group 6-12 years.

Wilson (1967) summarized data from many sources which demonstrate that the case-fatality rate for most series of cases of postvaccinial encephalitis was about 30%, with a reported low of 9% and a high of 57%.

Although host factors were certainly involved in a disease believed to have an immunopathological basis (see Chapter 3), the strain of virus appears to have been important in determining the frequency of postvaccinial encephalitis. The New York City Board of Health strain, which was the principal strain used in the USA, appears to have been the least likely of the widely used strains to cause it, closely followed by the Lister strain. Indeed, the frequencies recorded by Neff et al. (1967) and Lane et al. (1969) for individuals over 1 year of age were so low that they could almost be accounted for by the coincident occurrence of encephalitis due to other causes. However, the rate was much higher in the 10-state survey reported by Lane et al. (1970b).

Although there is no single laboratory test that can satisfactorily determine the virulence of vaccinia virus for man or assess the likelihood that vaccination will cause postvaccinial encephalitis, investigations by Marennikova et al. (1969) in mice and rabbits were consistent with the following classification of several strains in terms of their pathogenicity: mildly pathogenic—New York City Board of Health and EM-63; moderately pathogenic—Lister, Bern and Patwadangar; and highly pathogenic—Copenhagen, Tashkent and Ikeda (see Chapter 11, Table 11.20).

Several different strains of vaccinia virus were used in Belgium and the Netherlands during the 1950s; the incidence of post-vaccinal encephalopathy in infants dropped substantially after the Lister strain was introduced in the Netherlands in 1963 (Table 7.9). In Switzerland and Austria the number of reported cases of postvaccinal encephalitis fell dramatically after the Bern strain was replaced by the Lister strain in 1962 and 1967 respectively (C. Fleury, personal communication, 1967; Berger & Heinrich, 1973).

### Contraindications to Vaccination

During smallpox eradication programmes in areas in which smallpox was endemic, WHO recommended that no contraindications to vaccination should be envisaged—for two reasons. First, the risk of smallpox infection was considered to be significantly greater than the risk of complications and, secondly, most vaccinations were carried out by personnel without medical training, who could not be expected to diagnose correctly conditions such as eczema. However, it was

recommended that very sick individuals should not be vaccinated, because their subsequent death might be attributed to vaccination. On the other hand, in countries in which smallpox was not endemic, special attention was paid to contraindications to vaccination. Instructions as to what physical conditions should be regarded as constituting contraindications varied according to national health legislation, but the following 4 conditions were generally accepted:

(1) *Immune disorders.* These included agammaglobulinaemia, hypogammaglobulinaemia, neoplasms affecting the reticuloendothelial system and the use of immunosuppressive drugs. Such conditions substantially enhanced the risk of the most serious complication of vaccination—namely, progressive vaccinia.

(2) *Eczema.* Vaccination was contraindicated in persons who were currently suffering from eczematous skin lesions or whose family included an individual with eczema, because of the risk of eczema vaccinatum in either the vaccinee or the family member concerned. However, it was always difficult to exclude from vaccination persons

Table 7.9. Cases of encephalopathy after the vaccination of infants less than 1 year of age in the Netherlands, 1959-1970<sup>a</sup>

Period	Number of vaccinations	Vaccinia strain	Number of cases <sup>b</sup>	Number of cases per million vaccinations
1959-1962	821 000	Copenhagen	31 (16)	37.7
1963-1970	1 708 000	Lister	19 (11)	11.1

<sup>a</sup> Based on Polak (1973).<sup>b</sup> Figures in parentheses indicate numbers of deaths.

who had suffered from eczema in the past but did not have active skin lesions; such persons sometimes experienced eczema vaccinatum.

(3) *Pregnancy.* It is a general principle to avoid immunization in pregnancy. This policy was followed with smallpox vaccination, because of the risk (admittedly rare) of fetal vaccinia, a usually fatal condition.

(4) *Disorders of the central nervous system.* In order to minimize the risk of postvaccinal encephalitis, disorders of the central nervous system in the person to be vaccinated, or in family contacts, were accepted as contraindications in many countries. However, there is no evidence that the exclusion of such subjects affected the incidence of that complication.

In addition to the above 4 generally accepted contraindications, in some countries vaccination was considered undesirable for persons with an acute infectious disease (influenza, measles, etc.), a chronic infectious disease (e.g., tuberculosis) or an allergic constitution, or for persons who had been immunized against other diseases such as yellow fever, cholera, or typhoid fever on the same day as the scheduled smallpox vaccination. The justifications were, respectively, the hypothetical risk of complications arising from infection with vaccinia virus in persons whose physical condition was not normal at the time, and the belief that an interaction between the different immunizing agents might prevent the occurrence of a proper immunological response.

In most countries in which smallpox was endemic, leprosy was also present. Since primary smallpox vaccination often precipitated reactions such as erythema nodosum leprosum or neuritis in leprosy patients (Webster, 1959), health officers in these areas had to determine whether patients with lepromatous symptoms should be vaccinated. The WHO recommendation was that leprosy, including lepromatous leprosy, should not be a contraindication in such circumstances,

since the risk of smallpox infection was substantially greater than that posed by the reactions concerned (Browne & Davis, 1962).

### Prevention and Treatment of Complications

#### *Immunoprophylaxis and immunotherapy*

Human antivaccinia immunoglobulin (vaccinia-immune globulin), prepared from the plasma of recently vaccinated persons, became available in the early 1950s. Potency requirements were that it should contain at least 500 IU of vaccinia antibody per ml, in terms of the International Standard for Anti-Smallpox Serum (WHO Expert Committee on Biological Standardization, 1967).

It was thought that since some of the more severe complications of vaccination were caused by defects in antibody production, the administration of vaccinia-immune globulin at the time of vaccination might prevent such complications, without inhibiting an active immune response. Nanning (1962) reported on a field experiment in the Netherlands in which about 100 000 army recruits were vaccinated, half of them given vaccinia-immune globulin and the other half a placebo. There were 3 cases of central nervous system complications in the vaccinia-immune globulin group and 13 in the placebo group. No study of similar magnitude was conducted elsewhere, but in the Netherlands vaccinia-immune globulin was subsequently used in all primary vaccinations of adults (Polak, 1973). Vaccinia-immune globulin was also recommended for the prevention of eczema vaccinatum, being administered at the time of vaccination, whenever an eczematous child had to be vaccinated because of special circumstances, such as exposure to a case of smallpox (Sharp & Fletcher, 1973).

Kempe (1960) analysed 300 cases of severe complications of vaccination treated with vaccinia-immune globulin. There was no evidence that it influenced the course of

postvaccinal encephalitis, but observations on 132 treated cases of eczema vaccinatum suggested that it reduced the mortality from the usual level of 30-40% to 7%. It was also useful in treating 28 cases of accidental auto-inoculation with vaccinia virus, and led to the prompt cessation of the development of new lesions in 62 patients with generalized vaccinia. However, vaccinia-immune globulin was much less effective in treating cases of progressive vaccinia, because the major immunodeficiency in these cases was in cell-mediated immunity. Vaccinia-immune globulin administration was associated with the production of neutralizing antibody in cases of eczema vaccinatum, generalized vaccinia and progressive vaccinia. Kempe treated all subjects who presented, holding that the cases were few in number and occurred only sporadically and that the early indications of the value of the treatment made it ethically difficult to withhold its use. In another study, Sharp & Fletcher (1973) observed rapid improvement within 48 hours of the administration of vaccinia-immune globulin to cases of generalized vaccinia, eczema vaccinatum and severe local vaccinal reactions.

#### *Chemotherapy*

In the 1950s and 1960s several chemicals were found to inhibit vaccinia virus replication in cell cultures and in laboratory animals. In addition to being investigated for the treatment of smallpox (see Chapter 1), they were tested for the treatment of complications of vaccination. The most effective substances in experimental systems were derivatives of cytosine arabinoside, rifampicin, a urea derivative of diphenyl sulfone, and a thiosemicarbazone derivative termed metisazone (*N*-methylisatin  $\beta$ -thiosemicarbazone). There was no evidence that any of them was effective, although Brainerd et al. (1967) reported that the use of metisazone had a beneficial effect in progressive vaccinia, a condition in which vaccinia-immune globulin was useless.

#### **Reconsideration of Vaccination Policies in Non-endemic Countries**

As smallpox transmission was interrupted in various countries, the occasional untoward results of routine vaccination gradually emerged as a public health problem, which

**Plate 7.10.** C. Henry Kempe (1922-1984). As Professor and Chairman of the Department of Pediatrics at the University of Colorado Medical Center, Denver, USA, Kempe was a major figure in the investigation of complications of vaccination in children in the USA during the 1950s and 1960s. He also participated in the extensive investigations of smallpox carried out with Dr A.R. Rao in Madras, India, over the same period.

concerned both the general public and health administrators. In essence, in smallpox-free countries routine vaccination was maintained or mass vaccination campaigns were undertaken in order to maintain a protective barrier against the spread of smallpox in the population, but this community benefit was gained at the expense of a few individuals who suffered from the complications of vaccination. For example, the last case of smallpox in the USA was reported in 1949 but routine vaccination continued until 1972. The national survey of vaccination in the USA during 1963 carried out by CDC (Neff et al., 1967) showed that among the 14 million persons who were vaccinated against smallpox in that year (6.2 million primary vaccinations and 7.8 million revaccinations), there were 132 cases of severe complications and 7 deaths. From the results of this survey, it could be roughly estimated that between 1949 and 1972 there may have been about 3000 cases of severe vaccinal complications, with some 150 deaths.

Lane & Millar (1969) compared the projected number of deaths from routine vaccination in the USA for the 30 years from 1970 to 2000 with what might be expected if this

procedure were replaced by vaccination of only high-risk groups (military draftees, hospital workers and international travellers), in combination with ring vaccination of contacts (at most 5000 per importation) and occasional mass vaccination campaigns to control smallpox outbreaks resulting from importations. They concluded that there might be 210 vaccination deaths if routine vaccination were continued, compared with 60 deaths from the vaccination of high-risk groups. There would have to be 21 separate importations of smallpox to make up the difference of 150 deaths; but no cases had been imported into the USA during the previous 20 years and the risk was constantly diminishing. Dick (1973) carried out a similar kind of calculation for the United Kingdom and concluded that on the basis of the mortality due to vaccination in that country there would be 150 such deaths if routine vaccination were continued—a figure that would be equalled by the number of smallpox deaths only if there were 50 importations of variola major over the 30 years between 1970 and 2000, compared with the 13 which had occurred during the preceding 20 years. It is clear that routine vaccination in the United Kingdom and the USA, and by analogy in other countries which had long since eliminated smallpox, entailed a cost which had been acceptable when there was a substantial risk of smallpox, either endemic or imported, but which was not justified when the risk had become very slight.

Aside from the risks inherent in routine vaccination, complications posed a severe problem when a country in which smallpox was not endemic conducted mass vaccination for the containment of an outbreak following an importation. For example, in 1963 smallpox was imported into Sweden from an unidentified Asian country. Twenty-seven cases resulted. A voluntary mass vaccination campaign was performed in which about 300 000 persons in central Stockholm were vaccinated in the course of a few weeks (Ström & Zetterberg, 1966). As a result of the vaccination campaign, 77 persons suffered vaccinia complications (neurological complications, 14; carditis, 7; eczema vaccinatum, 7; and postvaccinia exanthema, 49). Without vaccination, of course, there would have been many more than 27 cases of smallpox.

These experiences provoked substantial debate among research workers and health planners during the 1960s as to whether it was

justified to continue routine smallpox vaccination in countries in which smallpox was no longer endemic (Benenson, 1974; Dick, 1966, 1971, 1973; Kempe & Benenson, 1965; Langmuir, 1974). This was not a new debate. In the geographically isolated country of Australia compulsory vaccination had been adopted in only 2 of the 6 states, and Cumpston (1914) calculated that only about 30% of the children born in Australia between 1860 and 1910 had ever been vaccinated. "Conscience clauses" introduced into legislation enacted in the states in which compulsory vaccination of infants was operative reduced the proportion of newborn infants vaccinated each year to less than 10% by 1923 (Cumpston & MacCallum, 1925). The responsible state and Commonwealth health officers repeatedly inveighed against this laxity in vaccination, but the state governments took no action. The situation in New Zealand was similar. The threat of smallpox was never perceived as great enough to justify the enforcement of an unpopular measure, and even the large outbreak of variola minor in New South Wales in 1913–1917 (see Chapter 8) was not enough to cause the parliament of that state to pass a compulsory vaccination act.

By the late 1960s, several countries of Europe and those of North America had already discontinued compulsory routine smallpox vaccination programmes, but it was still common for paediatricians to recommend that children should be vaccinated, usually during the 2nd year of life. The reason for this recommendation was that it was believed that complications were less common when primary vaccination was carried out in childhood; moreover, the International Health Regulations, as applied in many non-endemic countries, made the possession of a valid smallpox vaccination certificate almost a *sine qua non* for international travel.

### Complications: the Overall Picture

The complications arising from vaccination against smallpox clearly posed a serious public health problem in the non-endemic countries. Several steps were taken to mitigate its effects, notably the substitution of "milder" strains of vaccinia virus, such as the New York City Board of Health and the Lister strains, that caused fewer complications, the

postponement of vaccination until the 2nd or 3rd year of life (which greatly reduced the risk of postvaccinal encephalopathy), the use of vaccinia-immune globulin for the treatment of complications and the development of more attenuated strains of vaccinia virus (see Chapter 11). Nevertheless, there was an irreducible minimum rate of complications, and even normal primary vaccination was associated with unpleasant local and general reactions. The ultimate solution was the discontinuation of vaccination, which could be done without argument only if smallpox were eradicated globally. In addition, universal discontinuation of smallpox vaccination would result in a substantial saving in health budgets covering vaccination programmes and the medical care of patients suffering from complications. These considerations had begun to preoccupy the world scientific community during the 1950s and 1960s, and constituted one of the reasons for promoting the development of the global smallpox eradication programme.

## PROGRAMMES FOR VACCINATION AND REVACCINATION

### Vaccination and Revaccination of the General Public

By the middle of the 20th century, smallpox vaccination had become part of the routine immunization programme of most countries in the world. The recommended age for vaccination varied from country to country, but it was common practice for primary vaccination to be done during the first 2 years of life and revaccination performed when children entered and left primary school. The first report of the WHO Expert Committee on Smallpox (1964) recommended that in countries in which smallpox was endemic, primary vaccination should be carried out as early as possible, preferably in the neonatal period, and repeated about 12 months later. For revaccination, a 5-10 year interval was recommended for the non-endemic countries and one of 3 years for the endemic countries. In North America and some European countries, hospital staff were, in theory, obliged to be vaccinated every 3 years, but as smallpox faded from memory this requirement was rarely enforced.

Because of the relatively high incidence of postvaccinal encephalopathy among infants

in the USA revealed by the CDC surveys, it was recommended that primary vaccination should not ordinarily be carried out during the first 2 years of life. On the other hand, public health experts in many European countries, noting that the highest incidence of postvaccinal encephalitis was in adolescents undergoing primary vaccination, recommended that this immunization should be performed during the 2nd year of life.

### Simultaneous Vaccination with Several Antigens

Smallpox vaccination was often carried out at approximately the same time as immunization with diphtheria and tetanus toxoid or with inactivated antigens of pertussis, typhoid and poliomyelitis, since it was considered that such a practice was safe and did not interfere with the immune responses to each agent (Winter et al., 1963). However, it was important not to use the same arm for the injection of bacterial antigens as had been used for the inoculation of smallpox vaccine a few days earlier, in order to avoid the severe febrile reactions that occasionally resulted (A. S. Benenson, personal communication, 1982).

Studies were carried out during the 1950s and 1960s to find out whether the combined use of various live vaccines would affect their safety and efficacy. The simultaneous administration of oral poliovaccine and smallpox vaccine caused no particular problems either in terms of increased side-effects or reduced take rates (Karchmer et al., 1971; Winter et al., 1963). Other studies showed that combinations of smallpox vaccine, BCG vaccine (Lin, 1965), yellow fever vaccine (Meers, 1960), and measles vaccine (Breman et al., 1975) were safe and produced good immune responses. In these studies, separate vaccines were administered simultaneously at different sites. However, when smallpox, measles and yellow fever vaccines were combined and inoculated by jet injection into the same site, there were no untoward effects but the immune response for yellow fever virus was reduced (Meyer et al., 1964b). When smallpox, yellow fever, measles and diphtheria-pertussis-tetanus (DPT) vaccines were administered at separate sites by jet injection, the response to smallpox vaccine was unaffected but the measles seroconversion rate dropped from 89% (if DPT was not given) to 70% (Ruben et al., 1973). However, this apparent decrease

was not observed in later studies, and simultaneous administration of the antigens commonly used in developing countries in the 1970s was generally regarded as safe and efficacious (Foege & Foster, 1974). In practice, the commonest combinations were smallpox and yellow fever vaccines (in much of francophone Africa) and simultaneous immunization against smallpox and measles, in the CDC-assisted programme in western and central Africa (see Chapter 17). Smallpox and BCG vaccinations were given simultaneously but in opposite arms in many countries in central and eastern Africa.

### Vaccination of International Travellers

The 1944 International Sanitary Convention (United Nations Relief and Rehabilitation Administration, Health Division, 1945) amended the previous Convention, formulated in 1926, and devised a vaccination certificate (Plate 7.11), which required that the vaccinal reaction should be inspected 8–14 days after the primary vaccination and 48 hours after revaccination. A certificate was not valid for more than 3 years.

On 9 April 1951, a special committee on the drafting of the International Sanitary Regulations (the former International Sanitary Conventions) met in Geneva (World Health Organization, 1951a). During the Committee's sessions, the original draft form of the vaccination certificate was extensively amended (World Health Organization, 1951b; Plate 7.12A). As revised (Plate 7.12B), this form was adopted by the Fourth World Health Assembly on 25 May 1951. When, in 1981, the vaccination of travellers against smallpox was no longer a requirement a stamp was used to cancel the smallpox vaccination certificate but the form was still in use for other vaccination requirements. In 1983 it was replaced by a new form lacking any provision for smallpox vaccination (see Chapter 28, Plate 28.1).

As early as 1945, the authorities concerned with the International Sanitary Convention stipulated that, in relation to vaccination certificates, "recent vaccination shall be taken as meaning evidence of successful vaccination not more than 3 years or less than 14 days previously, or evidence of an immune reaction" (United Nations Relief and Rehabilitation Administration, Health Division, 1945). In 1956, the WHO Committee on Interna-

International Sanitary Convention, 1944.

**INTERNATIONAL CERTIFICATE OF VACCINATION  
AGAINST SMALLPOX**

THIS IS TO CERTIFY THAT  
(Age ..... Sex ..... ) whose signature appears below has  
this day been vaccinated by me against smallpox.  
Origin and Batch No. of vaccine .....

Official Stamp	Signature of Vaccinator .....
	Official Position .....
	Place ..... Date .....

Signature of person vaccinated .....

Home Address .....

**Important Note:** In the case of primary vaccination the person vaccinated should be warned to report to a medical practitioner between the 8th and 14th day, in order that the result of the vaccination may be recorded on this certificate. In the case of revaccination the person should report within 48 hours for first inspection in order that any immune reaction which has developed may be recorded.

THIS IS TO CERTIFY THAT the above vaccination was inspected by me on the date(s) and with the result(s) shown hereunder:

tional Quarantine noted that although these rules "may lack a firm scientific basis, they are nevertheless administratively expedient in order to avoid delay to persons on an international voyage" (World Health Organization, 1956). The maximum interval of 3 years, in particular, lacked a carefully documented basis, although Marsden (1936) had discovered no cases of variola minor in persons vaccinated less than 7 years earlier, and before that Hanna (1913) had found that variola major was rare and mild in children under 4 years of age who had been vaccinated in infancy, but severe (case-fatality rate, 45%) in unvaccinated children in that age group (see Chapter 1, Table 1.11). Subsequently, Rao (1972) reported that only 90 out of 2181 cases of variola major in children under 4 years of age occurred in those with a vaccination scar.

Nyerges et al. (1972) reported that the levels of neutralizing antibody 3 years after the last revaccination were as high as those found 3 weeks after primary vaccination. Taking the absence of rises in the level of

Appendix 4 Annexe 4

INTERNATIONAL CERTIFICATE OF VACCINATION OR REVACCINATION AGAINST SMALLPOX  
CERTIFICAT INTERNATIONAL DE VACCINATION OU DE REVACCINATION CONTRE LA VARIOLE

This is to certify that  
Je soussigné certifie que

whose signature follows  
dont le dessous suit

has on the date indicated been vaccinated or revaccinated against smallpox,  
a été vacciné ou revacciné contre la variole à la date indiquée.

Date	Signature and professional status of vaccinator Signature et qualité professionnelle du vaccinateur	Signature and status of holder Signature et statut du titulaire	Result Résultat	Date of other vaccination Date de toute autre vaccination
1			1	1
2			2	2
3			3	3
4			4	4

The result of vaccination or revaccination to be recorded in the following notations:  
Le résultat de la vaccination ou de la revaccination doit être indiqué de la manière suivante:

POSITIVE or POS. when an accelerated vesicular reaction (vaccinoid) appears between the fifth and eighth day inclusive, or if a typical pustular vaccinal reaction occurs.  
POSITIF ou POS. lorsque une réaction vésiculaire accélérée (vaccinoïde) se manifeste entre le cinquième et le huitième jour (inclus), ou en cas de réaction pustuleuse typique (vaccinale).

NEGATIVE or NEG. when no reaction or only non-vesicular reaction appears during the four days following the vaccination.  
NÉGATIF ou NÉG. lorsque aucune réaction ou réaction non-vésiculaire apparaît pendant les quatre jours suivant la vaccination.

The term "Reaction of immunity" will not be used.  
Le terme "Réaction d'immunité" ne sera pas employé.

This certificate is valid for three years from the date of vaccination or most recent revaccination.  
Ce certificat est valide pendant trois ans à compter de la date de la vaccination ou de la dernière revaccination.

The professional status of the vaccinator must be certified by the health authority or by any other person qualified to do so by the Government of the territory where the certificate was issued or where the subsequent vaccination took place. If the vaccinator is a member of a national or local health service or the Armed Forces of a State, the placing on the certificate of the official stamp of his service will suffice. In the case of the Armed Forces, the location of the issuing unit is not required.  
Le statut professionnel du vaccinateur doit être certifié par l'autorité sanitaire ou par toute autre personne qualifiée à cet effet par le Gouvernement du territoire où le certificat a été délivré ou où la vaccination ultérieure a eu lieu. Si le vaccinateur est membre d'un service sanitaire national ou local ou des Forces armées d'un État, l'apposition sur le certificat du cachet officiel de son service suffira. Dans le cas des Forces armées, l'indication de l'unité émettrice n'est pas requise.

Any amendment or erasure of this certificate, or failure to complete any part of it, may render it invalid.  
Toute modification ou effacement de ce certificat, ou omission de remplir une quelconque des mentions qu'il comporte peut affecter la validité.

The validity of this certificate shall extend for a period of three years, beginning eight days after the date of a successful primary vaccination or, in the event of a revaccination, on the date of that revaccination.  
La validité de ce certificat couvre une période de trois ans commençant huit jours après la date de la primo-vaccination effectuée avec succès (prix) ou, dans le cas d'une revaccination, le jour de cette revaccination.

The approved stamp mentioned above must be in a form prescribed by the health administration of the territory in which the vaccination is performed.  
Le cachet d'autorisation doit être conforme au modèle prescrit par l'administration sanitaire du territoire où la vaccination est effectuée.

Any amendment of this certificate, or erasure, or failure to complete any part of it, may render it invalid.  
Toute correction ou effacement de ce certificat ou l'omission d'une quelconque des mentions qu'il comporte peut affecter la validité.

B

**Plate 7.12. A:** The form proposed to the Fourth World Health Assembly in 1951, by the committee drafting the International Sanitary Regulations. **B:** The revised form approved by the Health Assembly.

haemagglutinin-inhibiting antibodies after revaccination as evidence of resistance to viral infection, these investigators found that such resistance increased with each successive 3-year revaccination, and suggested that the revaccination interval of health personnel at high risk could be prolonged beyond 3 years after 2 successful revaccinations. This result suggests that for international travellers the 3-year interval was conservative, but, as the WHO Committee on International Quarantine had concluded, it was administratively convenient, and continued to be accepted as long as vaccination certificates were required.

The day on which the certificate became valid after primary vaccination or revaccination was often debated at meetings of the WHO Committee on International Quarantine. The times agreed on in 1951—namely, 8 days after primary vaccination and the day after revaccination—were consistent with the earliest expected development of the immune response. Modifications, such as 12 or 14 days

after the date of both primary vaccination and revaccination, were suggested, and the obligatory inspection of the vaccinal reaction was questioned. In a sense, this debate is a reflection on the ways in which international committees sometimes operate, especially in the absence of a real problem.

It is clear from these discussions that national health administrations attached considerable importance to the use of vaccination certificates, regarding them as one of the most important measures for preventing importations of smallpox. However, although all agree that because possession of a vaccination certificate was mandatory more travellers were vaccinated than would otherwise have been the case, the importance of this requirement is challenged by some critics, who point out that it was subject to abuse. For example, certificates were not always examined by the appropriate health officer at the point of entry, and if a passenger had transferred at an intermediate port in a smallpox-free country his vaccination certificate might not have

been examined at all. Worse, perhaps, were instances of deliberate falsification, or the provision of certificates by travel agencies to unvaccinated customers. Persons who had an apparently valid certificate might nevertheless contract smallpox if the vaccine or technique used had been faulty.

The situation was at its worst during the 1960s and 1970s, a period of greatly increased

air travel, which reduced the travelling time between even the most distant endemic and non-endemic countries to a matter of hours. In earlier times, the inspection of all crew and passengers on ships from overseas ports to detect patients with smallpox had proved a useful method of limiting importations, especially into countries situated at some distance from endemic areas.

Summary: the global incidence of smallpox, 1900-1958	363

## INTRODUCTION

As has been described in Chapter 5, by the end of the 19th century variola major was endemic in most countries of the world and in every inhabited continent except Australia; and a new mild variety of smallpox, variola minor, was endemic in South Africa and the USA.

The present chapter explores the situation between 1900 and 1958 in greater detail than was given in the survey of the global incidence of smallpox in Chapter 4, drawing for the earlier data on Low (1918), Simmons et al. (1944-1954), Hopkins (1983a), various papers published in scientific journals, and records produced by national health authorities in several countries. It also traces in some detail the elimination of endemic smallpox in several countries in each continent in the years before 1958, which provided the rationale for the decision by the World Health Assembly to embark on a global smallpox eradication programme in 1959. Inevitably, because of the absence of reliable data from many countries and the inadequacy of the record even in those with the best data, the treatment of the subject is far from complete.

## VARIATIONS IN THE INCIDENCE OF VARIOLA MAJOR AND VARIOLA MINOR

As Fig. 5.8 (Chapter 5) illustrates, the American strain of variola minor (alastrim) virus spread from the USA to Canada, South America, Europe, Australia and New Zea-

land. Viruses that differed from alastrim virus in several biological properties (see Chapter 2) caused variola minor in Africa, and their spread is more difficult to trace. African variola minor was endemic in southern Africa until 1973, and a similar disease was reported from time to time in many countries of eastern and central Africa, usually coexisting with endemic variola major. It is not clear whether its extension in Africa was due solely to spread from the southern African focus or whether there were other places in Africa in which a similar mutant form of the virus emerged, or indeed whether some outbreaks followed importations of alastrim from the homelands of the European colonial powers.

One of the most interesting epidemiological features of smallpox during the period 1920-1958 was the relation between variola major and variola minor in countries in which both varieties occurred. An important factor affecting their relative incidence was the attitude of the public at large and public health workers to smallpox control; in general, both were much more tolerant of variola minor than of variola major. This was evident in many countries—for example, Switzerland, in which variola minor was endemic between 1921 and 1926. When variola major occurred in Basle in 1921 (44 cases; 7 deaths) it was promptly controlled, whereas it took 6 years to eliminate variola minor from Switzerland (Sobernheim, 1929), leading to a pronouncement by the Swiss delegate to the 1926 International Sanitary Conference of the Office international d'Hygiène publique:

"[Smallpox] has, in reality, no place in an international convention. It is not a pestilential

disease in the proper sense of the term: it is, in effect, a disease that exists everywhere. There is probably not a single country of which it can be said that there are no cases of smallpox." (Cited by Howard-Jones, 1975.)

Three other factors were operative: the infectiousness of individual patients; the number of contacts with susceptible subjects; and the degree of protection afforded by vaccination, if it had been carried out many years earlier. Patients with variola major usually excreted more virus and were thus more infectious than patients with variola minor, and variola major was more likely to overcome the effects of slight residual immunity due to vaccination. On the other hand, the severity of systemic symptoms from the prodromal stage onwards was so great in variola major that most patients were confined to bed and thus their contacts were greatly limited. Patients with variola minor usually had such a mild systemic illness that they were often ambulant throughout the course of the disease, and therefore made many more close contacts.

These four factors, and the element of chance, in relation to viral mutation or importation, interacted to produce four patterns of endemicity:

(1) In very well vaccinated communities, such as in many countries of continental Europe in the 1930s, the level of immunity of the population was so high that variola minor could not become established. Any smallpox that did occur was variola major associated with importations.

(2) In countries such as the United Kingdom and the USA, with highly organized health services but without properly enforced compulsory vaccination, outbreaks of variola major were rapidly brought under control by isolation and selective vaccination, whereas variola minor evoked no such reaction from the health authorities. For example, in Detroit, Michigan, in 1923, at a time when variola minor was epidemic (710 cases in 6 months), the Health Department conducted vigorous propaganda for vaccination, but achieved only about 6000 vaccinations per month. Soon afterwards variola major was imported from Canada; the vaccination rate increased very greatly, half a million persons being vaccinated within 1 month and 800 000 (about 70% of the population) within 5 months.

(3) In populous countries in which vacci-

nation was poor and the health services ineffective, such as India and Mexico, variola major predominated because of its greater capacity to infect and spread.

(4) In some African countries such as Ethiopia, in which at that time there was virtually no vaccination, endemic variola minor replaced variola major, probably during the 1950s. In this country of sparse population and very poor communications, the major factor favouring variola minor was probably its capacity to persist in small nomadic groups, among whom the transmission of variola major would have been interrupted spontaneously (see Chapters 4 and 21). Its persistence was probably helped by the widespread practice of variolation (see Chapter 21). For much of the period under review variola major and variola minor co-existed in many central, eastern and southern African countries.

Brazil does not fit readily into this classification. Although its health services were probably no better than those of Mexico during the 1920s and 1930s, alastrim replaced variola major in Brazil during the 1920s but never became endemic in Mexico.

## THE ELIMINATION OF SMALLPOX FROM EUROPE BY 1953

One of the factors which led to the decision by the Twelfth World Health Assembly, in 1959, to adopt global eradication of smallpox as a major goal of the World Health Organization (see Chapter 9) was the fact that by this time eradication had been achieved in all the countries of Europe and of Central and North America. Tables 8.1 and 8.2 set out the incidence of reported cases of smallpox between 1920 and 1958, in selected countries of western and eastern Europe respectively.

The gradual elimination of endemic smallpox from the countries of Europe is illustrated in Fig. 8.1-8.3. In the following pages the overall position in Europe between 1900 and 1958 is described first, drawing on Low (1918) for data before the First World War. Stowman (1945), Fabre (1948), Murray (1951) and the *Epidemiological and vital statistics report* (1953) provide useful summaries of the incidence during both the First and the Second World Wars and the inter-war period. Following this summary, the situation in selected European countries for which more

### Notes on the Statistical Tables

In order to illustrate the discussion presented in this chapter, a number of statistical tables are included to show the incidence of reported cases (rarely of reported deaths) in selected countries in various regions. The tables also show estimates of the populations of the countries listed near the beginning and end of the period for which the smallpox incidence is recorded, in order to give some indication of the sizes of the exposed populations. (The source of these population estimates is the United Nations *Demographic Yearbook, 1960* (United Nations, 1961) for the years 1920-1949 and *Population Prospects: Estimates and Projections as Assessed in 1982* (United Nations, 1985) for 1950 and subsequent years.)

Except in Portugal, Spain, the USSR and Mexico, most outbreaks of variola major in Europe and North America after about 1930 were due to importations and the numbers were reported reasonably accurately. However, experience in the Intensified Smallpox Eradication Programme showed that for countries of Africa, South America and Asia, the reported figures greatly underestimated the incidence, often representing no more than 1-2% of the true totals. In all countries in which variola minor was endemic, also, many cases were misdiagnosed or not reported. Nevertheless, the waxing and waning of the numbers of cases reported by various countries, as presented in these tables, reflect changes in the incidence of smallpox and provide evidence of its elimination from an increasing number of countries during the first half of the 20th century.

In each table the year considered by the authors to be the probable one in which endemic smallpox was eliminated from various countries is indicated by a horizontal line in the appropriate place; cases reported after this date are regarded as having been due to importations. As will be described in Chapter 23, such importations continued to occur in many countries until the mid-1970s. After endemic smallpox had been eliminated, outbreaks associated with importations rarely persisted for more than a few months.

It should be emphasized that just as the data on incidence given in the tables are often only an approximate indicator of the true incidence, it is also often impossible to determine in exactly which year smallpox ceased to be endemic in a particular country. After the Intensified Smallpox Eradication Programme had commenced operations, intensive surveillance made it possible to recognize the exact date of onset of the last case of endemic smallpox. In the period with which this chapter deals, however, smallpox sometimes just faded away; even the year in which the last endemic case occurred, let alone the precise date of its onset, is hard to determine. Where variola minor was prevalent, as in the USA, "smallpox" continued to be reported on the basis of faulty diagnoses after it had ceased to be endemic. The dates given for the elimination of endemic smallpox before 1958 are therefore sometimes a matter of judgement rather than of precise knowledge.

detailed data are available is described at greater length. The same procedure is used for the other continents.

The latter part of the 19th century had seen a great decline in smallpox in most countries of Europe, as glycerolated calf-derived vaccine became available, health services improved and vaccination and revaccination were practised more extensively (see Chapter 6). The decline continued during the early years of the 20th century, the incidence of smallpox being particularly low in the well-

vaccinated populations of Austria, Germany and the Scandinavian countries. In contrast, the Iberian peninsula continued to suffer from endemic smallpox with periodic severe outbreaks.

Low (1918) has summarized published information on the world-wide incidence of smallpox during the period before any international statistical organization existed; his report provides an invaluable source of data for the early part of the 20th century. Table 8.3 summarizes some of Low's figures on the

numbers of reported deaths from smallpox in various countries of Europe between 1900 and 1914. Because of the persistently high incidence of smallpox in Russia, travellers from that country were a particularly important source of importations of smallpox into its

Fig. 8.1. Number of countries in Europe in which smallpox was endemic at various times between 1920 and its continental elimination in 1953 based on the 30 political divisions operative in 1982—i.e., those shown in Fig. 8.2 together with Cyprus, Malta and Luxembourg (all non-endemic) and Turkey (see Fig. 8.11).

European neighbours, especially the Scandinavian countries and Germany. Fortunately, in view of the strong antivaccinationist movement prevailing there at that time, the British Isles were shielded to some extent from importations from mainland Europe, because of the small number of travellers from Russia. Importations from the colonies were also infrequent, because the long voyage by ship ensured that infected persons who had embarked during the incubation period became ill before arrival and could therefore be recognized and isolated. The last large outbreaks of variola major in the United Kingdom occurred in 1902-1903.

The disruption and mass movements associated with the First World War exacerbated the disease in Russia—it was particularly severe in Russian Poland—and from Russia it spread to Germany, Austria and Sweden. Smallpox remained endemic in Italy, Romania and Yugoslavia, and in the area that later formed the new state of Czechoslovakia, as well as in Portugal and Spain. In the aftermath of the First World War the situation became even worse. During 1918-1920 severe epidemics killed 28 000 persons in Italy, 14 000 in Portugal and 1500 in Germany; in the USSR 186 000 cases were

reported in 1919. For political reasons, Switzerland had sealed its borders throughout the First World War and this saved it from imported smallpox, which had been a major problem in the Franco-Prussian War of 1870–1871.

As countries recovered from the ravages of the war and as effective public health measures were reinstated, variola major became much less common. However, in the early 1920s alastrim was imported into the United Kingdom from the USA and became estab-

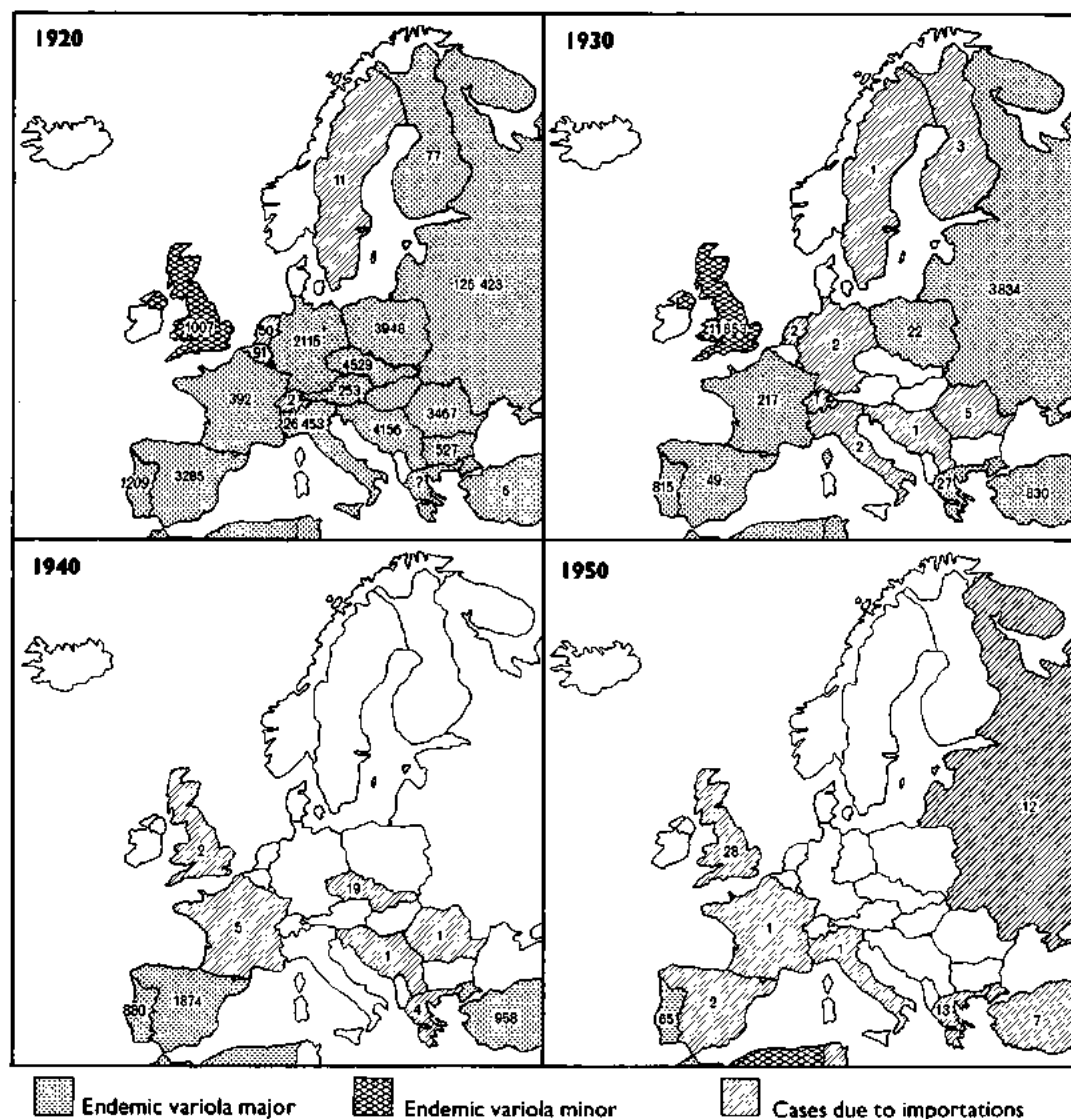

Fig. 8.3. Europe: countries with endemic variola major, endemic variola minor or with importations, and the number of reported cases of smallpox for the years 1920, 1930, 1940 and 1950. (Based on Jezek et al., 1982.)

lished there as an endemic disease, producing over 10 000 reported cases each year between 1926 and 1930. It was finally eliminated in 1934. It occurred in a few other European countries: "... in 1922 the mild non-fatal type was the rule in Finland, Germany, Switzerland, Egypt, Cuba, Jamaica, South Africa and parts of Canada and the United States, as well as the United Kingdom (England and Wales, Ministry of Health, 1923). Alastrim broke out in the Netherlands in 1929, and it occurred concurrently with variola major in Spain and Portugal in 1936. However, the only other

prolonged outbreak of variola minor in Europe was in Switzerland, in which over 5000 cases occurred between 1921 and 1926.

By the late 1930s endemic smallpox had been eliminated from most countries of Europe except Portugal, Spain (which experienced a resurgence after the Spanish Civil War, with over 1500 deaths in 1939-1940) and Turkey.

In contrast to the severe and widespread epidemics of smallpox in Europe after the First World War, only isolated incidents occurred during and after the Second World

War. Variola minor was imported into Italy from North Africa in 1944 and produced over 6000 reported cases before it was eliminated in 1947, while variola major occurred in Turkey during the war (over 12 000 reported cases in 1943; see Table 8.18) and extended from there to Greece.

From 1953 onwards Europe was free of endemic smallpox, but countries with colonial possessions in tropical regions—France, Portugal, the United Kingdom, and to some extent Belgium and the Netherlands—were especially liable to importations, rapid aerial transit of infected persons from endemic regions to Europe greatly increasing the hazard. Small outbreaks, often largely hospital-associated, occurred in all these countries (see Chapter 23).

### United Kingdom

Statistical data for the United Kingdom are provided separately for England and Wales, Scotland and Northern Ireland. Endemic smallpox was eliminated from Ireland in 1907 and subsequent importations were rare and quickly contained. Variola major was prevalent in Scotland from 1900 to 1905, with 6628 cases and 641 deaths, over half the cases occurring in Glasgow. From then on in only one outbreak did the number of cases exceed 80, but there were importations into the east coast ports from northern Europe and into Glasgow from Spain and the USA. Some cases of variola minor occurred in Scotland in 1927–1930 (maximum numbers reported: 154 in 1927 and 146 in 1928) as an extension of the much greater prevalence of the disease in England at that time. However, as is not surprising in view of the relative sizes of the populations of the constituent parts of the United Kingdom, the major brunt of smallpox was borne by England and the data for England and Wales are therefore discussed separately, and in greater detail, below.

#### England and Wales

*Variola major.* The last large epidemic of variola major in London occurred in 1901–1902, with 9496 reported cases and 1543 deaths, and there was an outbreak in Liverpool in 1902–1903, with 2280 reported cases and 161 deaths. Importations of variola major continued to cause small outbreaks in most years until about 1929, after which they

became fewer and were more rapidly controlled. The years 1939–1945 were characterized by an almost complete absence of smallpox, but there was an upsurge in 1946 and 1947, with many small outbreaks (Table 8.4). Variola major continued to be imported into England more frequently than into any other country of Europe for the whole of the period under review. The overall annual figures given in Table 8.4 do not accurately reflect the frequency of these importations. In 1946, for example, as British soldiers were being repatriated from distant parts of the world and with the post-war entry of students from Africa and Asia, no fewer than 15 separate introductions accounted for the 56 cases reported.

There were two reasons for the frequency with which smallpox was imported into the United Kingdom. The first was the extensive movement to and from endemic areas in Africa and Asia, associated with the country's imperial role and the traditions of movement that remained in the post-colonial period. The second was the fact, trenchantly criticized in the medical press (see, for example, *British medical journal*, 1962), that alone of the advanced industrial nations the United Kingdom had no requirement that overseas travellers should carry a valid international vaccination certificate. The latter situation was changed in 1963, when all persons seeking entry to the United Kingdom from an infected local area—in no matter what country—and from all countries of Africa, the Americas (except Canada and the USA) and Asia were required to produce a valid international certificate of vaccination. Especially in the period just after the Second World War, many of the importations were due to mild attacks of modified-type variola major in vaccinated servicemen (Murray, 1951). The low community acceptance of vaccination in infancy, even when it had been nominally compulsory (up to 1946), and the failure to vaccinate hospital workers regularly allowed such cases to infect others (especially hospital personnel) and thus to initiate outbreaks.

*Variola minor.* There were apparently a few small outbreaks of variola minor in England early in the 20th century (*Lancet*, 1903), one in Nottingham in 1901 being attributed to contaminated fomites sent from Salt Lake City, USA, to a Mormon convention (Boobyer, 1901), after which it spread to several other cities and then apparently died out.

<sup>a</sup> Based on Dixon (1962). Differences for some years from the numbers given in Table 8.1 are due to the use of different sources.

Interestingly, the only 2 importations of variola minor into Oceania—separate episodes in Australia and New Zealand in 1913—were attributed to Mormon visitors. Variola minor first appears to have become well established in England in 1919 (Copeman, 1920). Once again, it is difficult to trace its first occurrence, since it was often confused with chickenpox, but initially it seems to have been commonest in the north of England, with small pockets in the south. London was first affected in 1928.

Table 8.4 illustrates the remarkable difference in the incidence of variola major and variola minor in England and Wales during the period between the wars. Variola major was eliminated as an endemic disease early in the century, but subsequently often occurred as small outbreaks resulting from importations, which were always rapidly controlled. There were 35 such circumscribed outbreaks, with a total of 268 cases, in 14 out of the 24 years between 1935 and 1958. On the other hand, variola minor was a common endemic

disease from 1919 until 1934. When importations of variola minor did subsequently occur, as in 1952 and 1966 (the latter probably laboratory-associated; see Chapter 23), they caused many more cases (135 and 72 respectively) than did the outbreaks of variola major, the largest of which, in 1947, produced 48 cases before being brought under control.

Unquestionably, in the United Kingdom, as in the USA at about this time, the health authorities took variola major seriously and reacted effectively, with surveillance, the isolation of cases and the vaccination of contacts, but they paid relatively little attention to variola minor. It is perhaps not surprising that in the 1970s WHO officials experienced great difficulty in persuading the health authorities in Ethiopia to look upon variola minor as a disease of sufficient importance to make a call on their limited resources (see Chapter 21).

### **Russia and the Union of Soviet Socialist Republics**

Smallpox ravaged European Russia during the early part of the 20th century and was even worse during the misery that accompanied and followed the First World War. Russia was feared by its neighbours as a source of smallpox; ships from Russian ports were a recognized hazard in Scandinavia and most of the cases of smallpox in Germany were in areas near the eastern borders. Indeed in 1910 almost 30% of all cases of smallpox reported in Germany occurred in travellers from Russia (Jones, 1914).

With the establishment of the USSR in 1917, the new government took steps to control smallpox, and vaccination was made mandatory in a decree signed by V. I. Lenin in April 1919. In 1924, the Soviet vaccination law was modified to require vaccination in infancy and the revaccination of teenagers (Kravchenko, 1970). Nevertheless, smallpox continued, with severe epidemics in European Russia in 1931–1933 that led to intensified vaccination campaigns and the elimination of endemic smallpox in 1936 (Vasil'ev & Vasil'ev, 1982). Subsequently, outbreaks following importations were reported in 1950–1952, 1955, 1956 and 1958 (see Table 8.2). The last outbreak occurred in 1960, when an importation from India caused 46 reported cases and 3 deaths in Moscow (Baroian & Serenko, 1961; see Chapter 23).

### **Germany**

The German states had been among the first in Europe to adopt compulsory vaccination and revaccination and the comparative freedom of the Prussian armies from smallpox in the Franco-Prussian War of 1870–1871 testified to the effectiveness of these measures (see Chapter 6). By 1900 vaccination of the civilian population had reached a high level and variola major had ceased to be endemic. However, for economic reasons large numbers of foreign agricultural workers and skilled tradesmen were recruited from Russia, in which vaccination was poor and variola major still common. In consequence, there were many small outbreaks initiated by imported cases.

In the aftermath of the First World War there were outbreaks totalling several thousand cases between 1916 and 1922, when endemic smallpox was again eliminated. In spite of the devastation, there was almost no smallpox in Germany during and immediately after the Second World War, but importations, with limited spread, occurred in 18 of the 36 years between 1922 and 1958.

### **France**

During the early years of the 20th century smallpox was much commoner in France than it was in Germany. Vaccination in infancy was made compulsory in 1902, with provision for revaccination at 11 and again at 21 years of age, but the law was not enforced. Paris and Marseilles were the principal centres of infection, especially Marseilles, the main port of entry for passengers and merchandise from endemic countries of North Africa and western Asia. One noteworthy advance was in the French army, in which smallpox had been so severe during the Franco-Prussian War. From 1914 to 1917 the army did not report a single case of smallpox.

A few hundred cases were notified almost annually between 1920 and 1936, and minor outbreaks associated with importations occurred in most of the following years (see Table 8.1). There was little smallpox in France during the Second World War, but subsequently local outbreaks occurred almost every year until 1956, though they were usually quickly contained. Many were very mild, the original cases usually being diagnosed as chickenpox (Fabre, 1948).

### Portugal and Spain

During the first quarter of the 20th century Portugal, for long one of the most economically depressed countries of Europe, sustained endemic variola major at a level rivalling that of countries in Africa and Asia at that time (Amaral, 1960). Its larger neighbour, Spain, was not much better off, although the incidence was briefly reduced twice (in 1929 and again in 1937) only to rise again, notably in the aftermath of the Spanish Civil War. Classical variola major occurred throughout this period, but from 1944 to 1948 the overall case-fatality rate was only 3.1% and the reports indicated that both variola major and variola minor were present. Only variola minor occurred after that, until endemic smallpox was eliminated from both countries by the early 1950s.

### Scandinavia

Smallpox had been a severe disease in Sweden during the latter half of the 18th century, killing an estimated 10% of the population (see Chapter 6, Fig. 6.1). Compulsory vaccination was introduced in 1816 and greatly reduced the incidence but endemic smallpox was not eliminated until the end of the 19th century. There were small outbreaks almost every year during the first two decades of the 20th century (Table 8.5), due to importations. In 1917 a substantial outbreak occurred, associated with the passage of war invalids from Russia to Germany, but after 1920 there were cases in only 9 of the 43 years up to 1963, when an outbreak of variola major with 27 cases occurred, which was reported in great detail (Ström & Zetterberg, 1966).

Denmark and Norway, smaller countries with less international trade and travel than

Sweden, also remained free of endemic smallpox for the whole of the 20th century, but both countries occasionally reported single cases or very small outbreaks associated with importations.

The Scandinavian countries provided an example for the rest of the world. Subject to severe endemic and epidemic smallpox before vaccination became available, they eliminated smallpox by the end of the 19th century, and for the most part successfully excluded importations thereafter. When importations did occur, they were usually rapidly controlled.

### THE ELIMINATION OF SMALLPOX FROM NORTH AMERICA, CENTRAL AMERICA AND PANAMA BY 1951

The incidence of reported cases of smallpox in the USA, Mexico and Canada from 1920 to 1952 is shown in Table 8.6, and in the countries of Central America and Panama in Table 8.7. Two patterns are apparent in North America. The high incidence of smallpox in the USA from the beginning of the century was due mainly to variola minor with occasional outbreaks of variola major due to importations, and the situation was similar, on a smaller scale, in Canada. In Mexico, however, variola major occurred as a widespread disease from the beginning of the century, as it had during previous centuries (see Chapter 5). Variola minor was periodically introduced into Mexico from the USA but seems never to have become established there. Endemic smallpox was eliminated from all 3 countries by 1952.

### Central America and Panama

Early records are sparse for the 7 small states constituting Central America and Panama, located between Mexico in the north and Colombia in the south (see Fig. 8.6), but variola major appears to have been present in most of them during the early years of the 20th century (Low, 1918). However, from 1920 onwards most of these countries were free of endemic smallpox, although there were importations and outbreaks extending over several years in the more populous countries until the mid-1950s (Table 8.7).

<sup>d</sup> Only deaths (figures in italics) were reported between 1922 and 1943.

### United States of America

The history of smallpox in the USA in the period under review is dominated by the appearance of variola minor in Florida in about 1896 and its subsequent spread throughout the country and into Canada. This has been discussed at length by Chapin (1913, 1926) and Chapin & Smith (1932); the decline of smallpox after 1930 has been described by Dauer (1940). Table 8.8 sets out the numbers of reported cases of and deaths from smallpox from 1900 until the last cases occurred in 1949. The subdivision of annual totals of cases and deaths into variola major and variola minor derives in the main from Chapin & Smith (1932), who explored many sources in order to make their judgements about the variety of smallpox ("mild" or "severe") responsible for various outbreaks.

Variola major prevailed throughout the USA until the summer of 1897 but by then had disappeared from the country except for about 100 cases, with 30 deaths, which occurred in 16 different states. These local outbreaks were efficiently controlled and endemic smallpox appeared to have been eliminated (Chapin, 1913). However, during the first half of 1897 there were 54 cases of smallpox in Pensacola, Florida, and many more in the county in which Pensacola is situated, without a single death. From here the mild variety of smallpox, variola minor, spread through Florida, and in the year ending 31 March 1898, 3638 cases were reported, with only 51 deaths (case-fatality rate, 1.4%). Within a period of 4 years variola minor extended gradually over the whole of the continent north of the Mexican border (Fig. 8.4).

<sup>a</sup> A horizontal line beneath a figure indicates that this represents the last probable occurrence of endemic smallpox.<sup>b</sup> .. = data not recorded.<sup>c</sup> Figures in italics denote the number of reported deaths from smallpox.

The substrain of variola minor that was later called "alastrim" (see Chapter 2) remained the dominant form of smallpox in the USA thereafter. The number of cases notified each year represents at most 20% of those that actually occurred; many patients did not see a physician and many others who did were not reported as having smallpox. From the USA alastrim was exported to the United Kingdom (in 1902 and again in 1919), and to Brazil (1910), Australia (1913), New Zealand (1913) and the Philippines (about 1920). Against the background of endemic alastrim, repeated introductions of variola major occurred, mostly from Mexico (14 out of 23 outbreaks between 1915 and 1929) but also from Canada and overseas countries, especially Europe, during the early years of the century.

Chapin & Smith (1932) examined the detailed reports of as many outbreaks of variola major (the "severe type" of smallpox) as they could, in order to determine whether variola minor (the "mild type") ever gave rise to variola major. Their conclusion was that each variety of smallpox was due to a different subspecies of variola virus and that these "bred true". Subsequent experience in many parts of the world has confirmed this conclusion.

Although some cases of variola major were reported every year from 1900 until 1927, there were only 2 major outbreaks during this period. The first, in 1902-1903, affected particularly Boston, New York, Philadelphia, New Jersey and Ohio; variola minor was then prevalent in the Mid-West. The last large

epidemic of variola major in the USA occurred in 1924-1925, when some 7400 cases were reported, over one-third of them in 4 cities: Cleveland and Toledo (Ohio), Detroit (Michigan) and Pittsburgh (Pennsylvania).

Vaccination played an important role in both the progressive fall in the incidence of smallpox and in the replacement of variola major by variola minor. The virtual disappearance of variola major and the mild nature

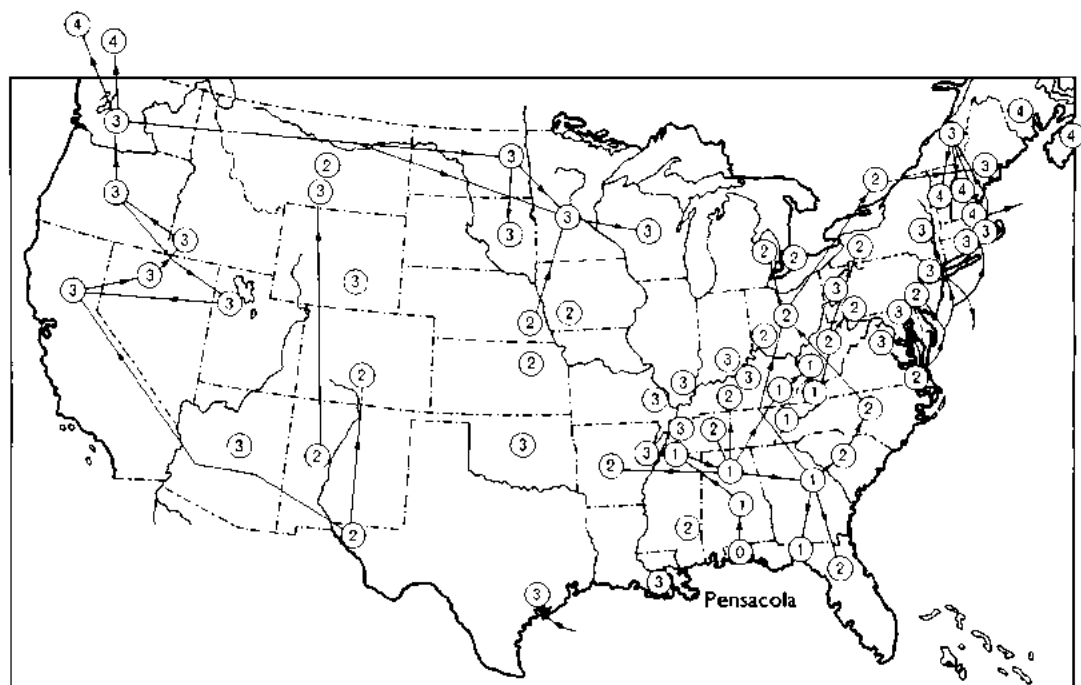

Fig 8.4. The spread of variola minor in the USA. It was first observed in Pensacola, Florida, in 1896. Figures in circles indicate the number of years elapsed between 1896 and the detection of cases in various cities in the USA including Alaska and in Canada. Arrows indicate directions of spread, when this could be determined, except for towns along the Mississippi, where the river was the route of spread. (Based on Chapin, 1913.)

NATIONAL LIBRARY OF MEDICINE, BETHESDA

**Plate 8.1.** Charles Value Chapin (1856-1941) was Superintendent of Health of Providence, Rhode Island (USA), from 1884 to 1932. A nationally renowned figure, he imaginatively translated newly emerging concepts of the epidemiology of infectious diseases and methods for their prevention into public health administrative practice.

of variola minor led to the emergence of antivaccinationist sentiments, although in 1922 the United States Supreme Court had ruled that school authorities had the right to require vaccination for admission to school (Vaughan, 1923). By the 1930s, 4 states of the USA had laws prohibiting compulsory vaccination, 28 states had no vaccination laws, 6 provided for local option and 10 had compulsory vaccination laws. The relation between the legal situation and the incidence of variola minor is illustrated in Fig. 8.5.

In the year 1927, for the first time, no case of variola major was reported in the USA, and apart from an outbreak in 1929 no further cases were notified until 1946. In that year a soldier returning from Japan introduced smallpox into Seattle, Washington, which resulted in an outbreak of 51 cases, with 16 deaths (Palmquist, 1947). In 1947 a man with undiagnosed haemorrhagic smallpox died in a Manhattan, New York, hospital. Twelve other persons were infected and in the panic occasioned by this outbreak over 6 million

Fig. 8.5. The effect of vaccination laws on the incidence of smallpox in various states of the USA, 1919-1928. (Based on Woodward & Feemster, 1933.)

New Yorkers were vaccinated (Weinstein, 1947). The last outbreak of smallpox in the USA occurred in Texas in 1949 (8 cases with 1 death), probably after importation from Mexico.

Although variola major was eliminated as an endemic disease in 1927, variola minor continued to be common in states without compulsory vaccination laws. Reporting methods changed in 1944, and it is impossible to get an accurate picture of the elimination of variola minor from the USA. Although

grossly underreported when it was common, it was probably incorrectly diagnosed and reported during the few years just before and after its elimination from the USA, during the latter half of the 1940s.

#### Canada

The situation in Canada reflected that in the USA, with variola minor as the commonest form of smallpox after it became established there early in the century. However,

control by vaccination was more easily achieved in this less populous country and endemic smallpox was eliminated by 1944.

### Mexico

The situation in Mexico in the earlier part of the 20th century contrasted starkly with that in Canada and the USA. Mexico had a population of about 14 million in 1920 and between 5000 and 13 000 smallpox deaths were reported every year in the 1920s (see Table 8.6), at that time the highest reported incidence in any country in the world (Hedrich, 1936). Variola minor appeared in Mexico in 1932, probably after importation from the USA, but it did not displace variola major, which caused a major epidemic with over 8000 deaths in 1942-1943. This led to an increased emphasis on vaccination, which became possible in many rural areas because of the development of roads. There was a rapid fall in the number of reported cases of smallpox, which continued to be of the variola major variety, and a change was made in reporting, from "deaths" to "cases" (see Table 8.6). The last case of smallpox in Mexico occurred in 1951, just after the Pan American Health Organization had launched its programme to eradicate smallpox from the Western Hemisphere (Rodrigues, 1975).

### SMALLPOX IN SOUTH AMERICA, 1900-1958

Variola major was endemic in all the larger countries of South America during the first decade of the 20th century (Fig. 8.6), with the highest incidence in Brazil and Chile (Table 8.9). Reporting was very poor; indeed, many countries concealed the existence of smallpox for fear of the imposition of quarantine restrictions by their neighbours (Low, 1918).

In 1910 variola minor was reported from South America for the first time, in Brazil, where eventually it displaced variola major, which remained common in Argentina and Chile in the 1920s. Epidemics of variola major were reported in Colombia in 1943 and 1947, in Bolivia in the 1940s, and in Ecuador up to 1962. The last large outbreak of variola major in South America caused nearly 10 000 deaths in Peru in 1941-1943. Within a few years of the decision by the Pan American Sanitary Organization in 1950 to eradicate smallpox

from the Western Hemisphere, Peru, Uruguay and Venezuela had eliminated the disease. Bolivia, Colombia, Ecuador and Paraguay followed in the early 1960s. By 1967, smallpox was still endemic only in Brazil, although there were importations from Brazil into Argentina, French Guiana and Uruguay after that date (Fig. 8.7).

### Brazil

By far the largest and most populous country in South America, Brazil experienced severe epidemics of variola major early in the 20th century. Following a major epidemic in 1904-1905 (3800 deaths in Recife; 3600 deaths in Rio de Janeiro) the Brazilian government passed a bill requiring compulsory vaccination, but an antivaccination campaign led to open revolt with riots. Large epidemics with many deaths occurred in 1907-1910.

Fig. 8.6. Mexico, Central and South America: year in which smallpox ceased to be endemic in each country (national boundaries as of 1982). Dates in parentheses (for Honduras and Peru) indicate the initial elimination of endemic smallpox, after which endemicity was again established before final elimination in the year shown.

a A horizontal line beneath a figure indicates that this represents the last probable occurrence of endemic smallpox.

b .. = no data recorded.

c Figures in italics denote the number of reported deaths from smallpox.

Fig. 8.7. Number of countries of the 13 in South America in which smallpox was endemic at various times between 1920 and 1971. National boundaries as of 1982.

Variola minor was introduced into Bahia from the USA in about 1910, whence it spread to the southern states of Brazil and eventually throughout the country, producing an estimated 250 000 cases in 1910-1911 (Aragão, 1911). During the outbreak in Paraná in 1910, some 6000 persons were infected but the case-fatality rate was only 2.3% (Carini, 1911). Mortality data over the next 20 years show that variola minor gradually replaced variola major as the commoner form of smallpox in Brazil, but as late as 1926 an epidemic of variola major in Rio de Janeiro caused 2200 deaths.

Although there were very few notifications over a period of several years in the late 1920s and early 1930s, variola minor had become established as an endemic disease and several thousand cases were notified every year from 1955 onwards. Further, Brazil became a major source of transmission of the disease to neighbouring countries, especially Argentina, a risk which continued until smallpox was finally eradicated from Brazil and thus from the whole Western Hemisphere in 1971.

### Other Countries

In most of the other countries of South America variola major was common and severe during the first two or three decades of the 20th century and was then replaced by variola minor. The latter declined in incidence and was finally controlled in the 1950s and 1960s (Fig. 8.6), although importations from Brazil continued to occur. Ecuador was unusual in that variola major persisted at a relatively high level until the early 1960s.

## SMALLPOX IN ASIA, 1900-1958

Asia is by far the most heavily populated continent, and China and India, vast countries with weak national public health services during the early part of this century, have long been regarded as the traditional homes of smallpox. The decline in the number of endemic countries in Asia since 1920 is shown in Fig. 8.8. Asia was the major focus of variola major throughout the first half of the 20th century, and until about 1950 smallpox was endemic in all of the more populous countries of the continent. In order to simplify discussion of this vast region, the data on eastern Asia, the Indian subcontinent and Afghanistan, and south-western Asia have been summarized separately.

Though the records of smallpox in many countries of Europe during the first half of this century are incomplete and seriously underestimate the incidence, they are very much better than those of any other countries except Australia, Canada, Japan, New Zealand and the USA. Data for China and the countries between China and India are very incomplete and reports by public health workers have been used to supplement the information provided by the official figures.

### EASTERN ASIA

In contrast to the situation on the Indian subcontinent, endemic smallpox was eliminated from most of the countries of eastern Asia before the initiation of the Intensified Smallpox Eradication Programme in 1967 (Table 8.10; Fig. 8.9).

Fig. 8.8. Number of countries of the 38 in Asia in which smallpox was endemic at various times between 1920 and 1975. National boundaries as of 1982.

<sup>b</sup> ... = data not recorded.

<sup>c</sup> Figures in italics denote the number of reported deaths from smallpox.

<sup>d</sup> Comprising present-day Democratic Kampuchea, Lao People's Democratic Republic, and Viet Nam.

<sup>e</sup> From 1951 onwards, the figures refer only to the Republic of Korea.

<sup>f</sup> Including Singapore.

<sup>g</sup> In Annex 1 of the *Final Report of the Global Commission for the Certification of Smallpox Eradication* (World Health Organization, 1980), the figure given for 1949 is 490 348. This seems an unlikely figure for the number of reported cases at that time (see Chapter 13). It derives from Henneberg (1961) and is not supported by data in the *Epidemiological and vital statistics report*, from which the figures in this table were derived.

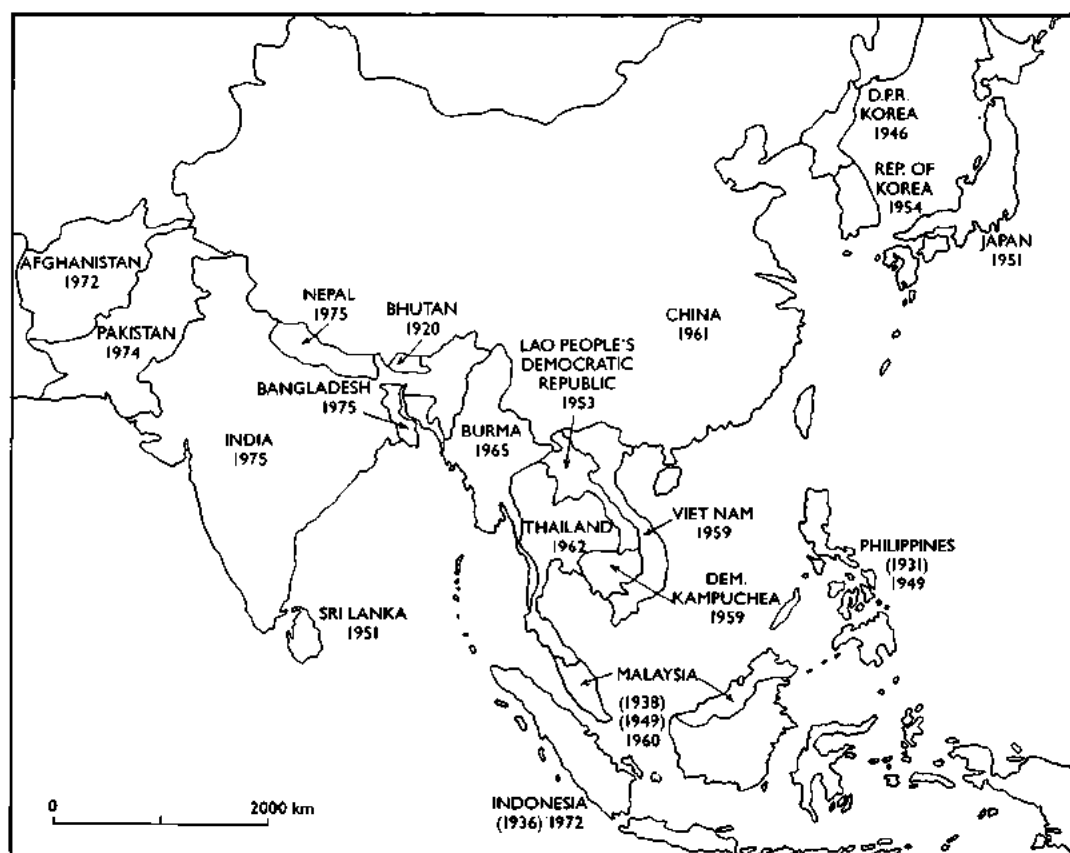

Fig. 8.9. East and South-East Asia: year in which smallpox ceased to be endemic in each country (national boundaries as of 1982). Dates in parentheses (for Indonesia, Malaysia and the Philippines) indicate the initial elimination of endemic smallpox, after which endemicity was again established before final elimination in the year shown.

For the first 3 decades of the 20th century smallpox was endemic throughout the mainland countries of eastern and south-eastern Asia, in Japan and in the larger island groups. Tibet, in which vaccination was not practised at all until 1940, suffered very severely, leading to the depopulation of some areas, and in China smallpox was regarded as something that every child had to get sooner or later. However, although there were still some severe epidemics, the incidence of smallpox declined in Japan, and notable early successes in eradication were recorded in the Philippines in 1931 and in the Netherlands East Indies (Indonesia) and the Federated Malay States (Malaysia) later that decade.

The disruption of services that accompanied and followed the Second World War led to a reappearance or resurgence of smallpox in several countries of eastern as well as of southern Asia. In Thailand, in which the

annual number of reported cases had been less than 1000 for many years, there was a major epidemic in 1945–1946, with more than 62 000 reported cases. Smallpox was reintroduced into Malaysia in the early 1940s and was not eliminated until 1949, and into the Philippines in 1948, but was eliminated again in 1949. Over 20 000 cases were notified in Korea in 1946, and a major epidemic, with upwards of 43 000 cases, occurred in 1951, during the hostilities in that country. The incidence in Japan rose to 17 800 in 1946, and smallpox was reintroduced into Indonesia in 1947, reaching epidemic proportions in 1949.

The fact that smallpox had been eliminated in Europe and North America was a powerful stimulus for the declaration by the World Health Assembly in 1959 that global eradication was a goal that could be achieved. Although it was not fully appreciated, even more impressive achievements—and more

relevant to the eradication of smallpox from the impoverished countries of Africa and the Indian subcontinent—were then in progress in China, the Korean peninsula and the countries of Indochina. The elimination of the disease in China will be described in some detail, since it ranks with eradication from India as one of the most significant achievements in the struggle against smallpox. Aspects of importance in the certification of smallpox eradication in China are described in Chapter 27.

### China

Smallpox was highly endemic throughout China for the first 4 decades of the 20th century, but no data were recorded except for the Treaty ports, from which most of the early figures in Table 8.10 were derived. Even here, they were gross underestimates. In Shanghai, as in the rest of China, smallpox was a seasonal disease, with a high incidence in winter and spring (from December to the end of May) and a low incidence during summer (Dold, 1915; Xu & Jiang, 1981). The disease was endemic, with epidemics in 1902, 1904, 1907, 1910 and 1913 (Dold, 1915) and between 1930 and 1951 there were epidemics in 1930-1934, 1936-1939, 1946-1948 and 1950-1951. Anecdotal data (Korns, 1921) reveal that smallpox was still wellnigh universal throughout China in the early 1920s; of 3020 adult males whom Korns questioned in an outpatient clinic, only 40 of 822 who had not been vaccinated had escaped the disease. Chinese with obvious pockmarks were very common in the streets of every city.

Variolation was practised on a small scale from about the 10th century (Needham, 1980) until the 1960s; outbreaks of smallpox in northeastern Yunnan Province in 1958 and in Nei Monggol Autonomous Region (Inner Mongolia) and Shanxi Province in 1963-1965 were attributed to variolation (see Chapter 27). From 1803 vaccination was occasionally available for those who could afford it. There were attempts to promote vaccination, notably after the establishment of the First Republic in 1913, but it was not practised at all extensively until the national smallpox eradication programme was instituted by the People's Republic of China in 1950.

Immediately after Liberation in 1949 a national campaign was launched to eradicate smallpox from China. The data published in

European languages are very limited (SME/79.10; SME/79.11, Fenner & Breman; WHO/SE/79.142 Rev.1; WHO/SE/79.151; Xu & Jiang, 1981), but give some impression of the nature and progress of this campaign. A particularly interesting feature was that eradication was achieved in all the cities and larger towns within 5 years, and throughout the country in 11 years, by the vigorous prosecution of mass vaccination, using liquid vaccine.

China has extensive areas of agricultural land supporting over 100 persons per square kilometre (Fig. 8.10) and many large cities. The population in 1950 was about 600 million. In contrast to the eastern part of the country, population densities throughout the whole of western China were very low and these parts were thus areas in which the endemic transmission of smallpox was unlikely to persist.

In October 1950, the State Council of the Central Government issued a "Notice on the Campaigns for Smallpox Vaccination of Autumn 1950" which expressed the formal decision to carry out a mass vaccination campaign for the whole population of mainland China. At the same time, the Ministry of Health announced "Temporary Regulations for Smallpox Vaccination", ruling that all children should be vaccinated 6 months after birth and revaccinated at the ages of 6, 12 and 18 years. The scheme of operation was developed by the Ministry of Health and comprised a massive propaganda campaign to enlist the support of the population (a "Mass Patriotic Health Movement"), the organization of the production and distribution of vaccine from 5 vaccine institutes located in various parts of the country, the mobilization and training of vaccinators and an intensive effort to achieve universal vaccination, mostly during the year 1951. The scheme also involved measures to control the possible spread of smallpox by travellers within China, by rail, sea and river (see below).

The 5 vaccine institutes, which produced liquid calf vaccine of the Temple of Heaven strain (see Chapter 11), were located in Beijing, Shanghai, Dalian (Dairen), Kunming and Lanzhou. There were initially some difficulties in producing enough vaccine for the campaign. Later some of these institutes ceased production, and new production centres were established (Table 8.11). Meetings were held to improve various aspects of vaccine production and eventually (after eradication had been achieved) freeze-dried

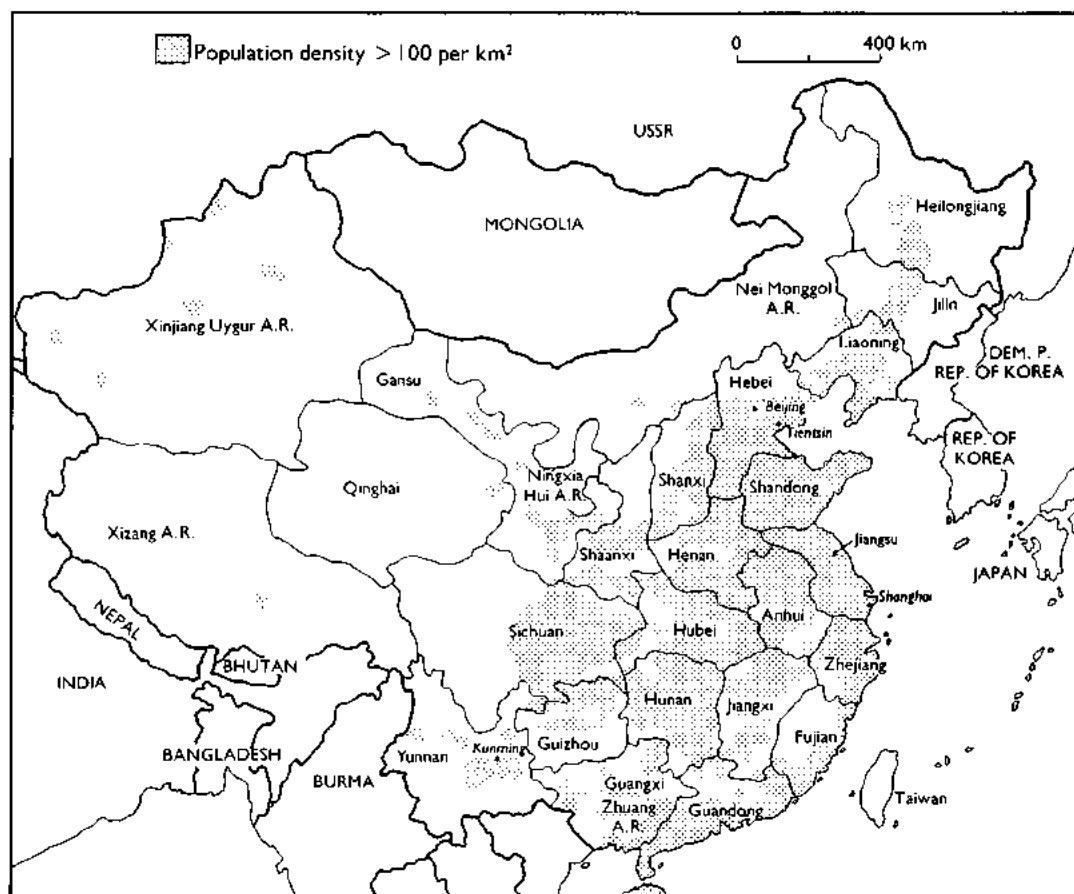

Fig. 8.10. China, showing the neighbouring countries and the provinces, autonomous regions and municipalities (internal boundaries as of 1985). The stippled area indicates regions where the population density is over 100 persons per square kilometre.

vaccine was produced for use in border and tropical areas. Vaccination was carried out by multiple pressure or the scratch technique, in 2 sites. The annual numbers of vaccinations performed throughout China during and immediately after the eradication campaign are suggested by the numbers of doses of vaccine issued (Table 8.12).

In 1955, following the endorsement by the State Council of the Central People's Government, the Ministry of Health produced a booklet, *Methods of Control of Communicable Diseases*, which provided for the compulsory notification of 24 diseases including smallpox. Between 1955 and 1958 a second country-wide mass vaccination campaign was undertaken, with technical aid provided by the USSR under the Socialist Pact of Friendship of 15 February 1950. This highly organized campaign operated airlifts in remote regions and was assisted by large numbers of personnel from Czechoslovakia and Hungary.

However, relations with the USSR gradually deteriorated with disagreements on borders and ideology, and by 1961 the assistance agreements had been cancelled.

The number of administrative divisions reporting cases dropped from 21 in 1953 to only 1, Yunnan, in 1959 (Table 8.13), although cases occurred in 2 localities in

Table 8.12. China: numbers of doses of smallpox vaccine issued, 1950-1963<sup>a</sup>

<sup>a</sup> No cases reported after 1965.<sup>b</sup> Data from Jiang (1985; and personal communication, 1987).<sup>c</sup> .. = data not recorded.<sup>d</sup> Importations.

Xizang Autonomous Region (Tibet) in 1960 and there were importations from Nepal in 1962 and 1964. Smallpox remained endemic in the south-west part of Yunnan, where there was a common border with Burma, until 1961 (see Chapter 27).

Information that only became available very recently (Jiang Yutu, 1985; and personal communications, 1984, 1987) reveals that smallpox continued to occur in China until 1965. In 1962, 6 years after the last reported case in the Nei Monggol Autonomous Region, 1 case was reported there, and in 1963 an outbreak of 283 cases occurred in Nei Monggol and nearby counties of Shanxi Province, with a further 30 cases in 1964. Another small outbreak (4 cases) occurred in Shanxi in 1965. Both the 1962-1964 and the 1965 outbreaks were attributed to the activities of variolators (see Chapter 27).

In 1959, because several outbreaks of smallpox had occurred following the importation of cases from neighbouring countries into China, it was decided to implement another general mass vaccination campaign. This began in 1960 and aimed to reinforce the achievement of the virtual elimination of smallpox and to raise the level of herd immunity and thus prevent the transmission of smallpox in the event of its importation into the country. Border areas were given first priority.

The method of implementation of the mass vaccination campaigns, in 1949-1952, 1955-1958 and in 1960, was unique. A directing committee of leaders was organized by the joint efforts of the health authorities and epidemic prevention departments in every province, municipality, and autonomous region. The committee was responsible for the organization of local health personnel and the training of medical and paramedical workers to form vaccination teams and perform the vaccinations. The teams went to each village or courtyard to vaccinate all persons, using the lists of names of members of the brigade or courtyard. Children in kindergartens and schools were vaccinated at these locations. During the first visit it was possible to vaccinate nearly 90% of the people. Others were vaccinated in the health centres or polyclinics. Members of governmental bodies, institutions, factories, etc., were vaccinated in health service facilities located at their place of work. After the communes were established in 1958, monthly payments by the State

were linked to evidence of vaccination of the family head and family members.

No general account of the country-wide smallpox eradication campaign in China has been published, but operations in the country's largest city and centre of communications, Shanghai, have been described (SME/79.11, Fenner & Breman; Xu & Jiang, 1981) and provide an idea of how the programme operated there and elsewhere. Details of special surveys made in Yunnan Province and in Xizang (Tibet) for certification purposes are described in Chapter 27.

### *Shanghai municipality*

Smallpox had always been endemic in Shanghai, with frequent epidemics, and before the eradication campaign was launched the overall vaccination rates were low (Table 8.14). A severe epidemic began in December 1950, 2 months after the promulgation of the eradication campaign. Although deaths and especially cases were underreported, 3167 cases and 1482 deaths were recorded for the 5 months December 1950 to April 1951.

The aim of the campaign in Shanghai was to vaccinate at least 95% of the population in the shortest possible time. In order to accomplish this, 6944 medical and paramedical personnel were organized into 1319 permanent stations and 1836 mobile vaccination teams. The personnel, comprising 3173 doctors of Chinese traditional medicine, 2067 doctors of western medicine, 455 nurses and midwives, 1126 medical students, and 123 others, were given a short training course in order to standardize the vaccination technique. The mass vaccination campaign began in March 1951. As the number of vaccinations rose (Table 8.15) and the weather became

hotter, the incidence of smallpox fell. The last case in Shanghai was reported on 26 July 1951.

During the early 1950s there was little international travel through Shanghai, but it was a major national communications centre, by sea, river, road and rail. The Quarantine Service was organized to cope with travellers by boat and train to other parts of China, as well as with boat-dwellers on the Huangpu and adjacent rivers. In the case of travellers by boat, ships' crews were mobilized to assist the campaign by propaganda and by forming "health groups" among them. Crew members were urged to report all cases of smallpox, among passengers or crew. An elaborate system was developed for supervising the issue of internal vaccination certificates for both boat and train travellers within China, with facilities for immediate vaccination if necessary.

Among the boat-dwellers on the Huangpu, in all 76 221 vaccinations were performed in 1951. Nine cases of smallpox were discovered on 5 boats; all case contacts were vaccinated and no other cases occurred. Among travellers and boat crews, 785 321 persons were vaccinated. On the 3576 boats that left Shanghai in 1951, 7 cases of smallpox were detected among passengers before boarding and 28 after boarding. In the first 4 months of 1951, 72 cases of smallpox were detected among intending train travellers. The effectiveness of this system of surveillance of travellers within China was demonstrated by the fact that although there was a major epidemic in Shanghai at the time, there was little apparent spread to other parts of China.

## Japan

Smallpox was endemic in Japan during the latter part of the 19th century, and during the early 20th century the country was constantly exposed to the risk of imported cases, owing to its large maritime trade and its proximity to China, Korea, Manchuria and Siberia, in all of which smallpox was a common disease at that time. Table 8.16 sets out the numbers of reported cases of and deaths from smallpox in Japan between 1892 and 1915.

Institutes for the production of vaccine in calves had been operating in Japan since 1874, and in 1891 arm-to-arm vaccination was prohibited. In 1896 celebrations were held in Ueno Park in Tokyo to mark the centenary of Jenner's discovery, and at about this time the famous bacteriologist Kitasato made important contributions to the preparation of bacteriologically sterile vaccine and helped to promote its use (Soekawa, 1984). In consequence of the gradual extension of vaccination the incidence of the disease fell. There was a severe epidemic in 1908, but thereafter smallpox continued to decline. In 1918 vaccination was made mandatory for all 1-year-old children and revaccination was carried out at school entry. The incidence fell further, and between 1927 and 1944 only 5412 cases were

Table 8.16. Japan: numbers of reported cases of and deaths from smallpox, 1892-1915<sup>a,b</sup>

Year	Number of cases	Number of deaths	Case-fatality rate (%)

reported (see Table 8.10). With the ending of the Second World War and the repatriation of Japanese soldiers, smallpox broke out again, with 1614 reported cases in 1945 and 17 800 in 1946. Shortly after this, control measures were further strengthened and smallpox ceased to be endemic in Japan in 1951.

### Korea

Korea was for several centuries an independent state within the Chinese cultural orbit, and its history of smallpox parallels that of China. In 1910 it was formally annexed by Japan, having for the 5 preceding years been a virtual protectorate of that country, but after the defeat of Japan in the Second World War, Korea was divided at the 38th parallel of latitude and separate governments have operated in the north and the south since 1953. During the period in which it was under Japanese control (1905–1945) the enforcement of country-wide vaccination reduced the prevalence of smallpox, but variola major remained endemic, with case-fatality rates in different outbreaks varying between 20% and 27%. There was a more severe epidemic than usual in 1940–1941, and the disruption after the Second World War led to a major exacerbation in southern Korea, with over 20 000 reported cases in 1946 and over 43 000 cases in 1951, during the hostilities (see Table 8.10). The situation was rapidly brought under control after the conclusion of the conflict, and endemic smallpox was eliminated in 1954.

### Indonesia

Severe outbreaks of smallpox occurred in various parts of the Netherlands East Indies in the early part of the century, an outbreak in Borneo claiming 3000 lives in 1905 and another, in Java, in 1913, causing more than 18 000 cases, with 5000 deaths. A severe outbreak occurred in Java in 1918–1919 and during 1922 and 1924 it spread to the outer islands, the south-eastern part of Borneo and the east coast of Sumatra.

In the early 1920s several thousand cases were reported annually, mostly in Java, but the incidence declined steadily after 1926 (see Table 8.10). Polak (1968) attributes the fall to more complete and effective vaccination coverage of the population, which was achieved by a combination of administrative and technical factors. Administratively, a system of

concurrent primary vaccination and revaccination, which had led to repeated revaccination of readily accessible subjects and inadequate primary vaccination coverage of infants, was replaced by a dual system with an allocated time for each. Primary vaccination of children aged 3–6 months was carried out by locally based vaccinators during the first 8 weeks of each quarter, and revaccination of the older population was performed during the last 5 weeks. Arrangements for supervision were also greatly improved. The main technical advance was the production by Otten (1927) of a stable air-dried vaccine for use in remote areas (see Chapter 7, Plate 7.3A). The control of smallpox did not depend just on mass vaccination, however, because it was the practice of the Dutch at that time vigorously to contain such outbreaks of smallpox as were found.

After 1933, about 10% of the population were vaccinated or revaccinated each year and by 1937 endemic smallpox had disappeared. Seven of the 21 cases reported between 1937 and 1940 (see Table 8.10) were documented as importations; the others were suspected to be importations or mistaken diagnoses (Polak, 1968). The disruption of the Second World War, during which the Netherlands East Indies and neighbouring areas of south-eastern Asia had been captured by the Japanese and then liberated in 1945, led to major epidemics of smallpox in neighbouring countries, especially Thailand and Malaysia. Smallpox was reintroduced into Sumatra from Thailand in 1947. This outbreak was controlled, but another importation from Malaysia led to a major epidemic in Java in 1949, with over 13 000 cases. This time the disease became firmly entrenched in the larger islands, but did not spread to the numerous but more sparsely populated islands to the east (see Chapter 13, Fig. 13.3). There was a sustained high incidence in 1950 and 1951, and although the number of reported cases fell after 1951, variola major remained endemic for some years after the Intensified Smallpox Eradication Programme was established in 1967. Eradication was finally achieved, for the second time, in 1972 (see Chapter 13).

### Philippines

There were as many as 40 000 smallpox deaths annually in the Philippines at the turn of the century, and smallpox was implicated

in about one-third of the cases of blindness (Low, 1918). Intensive vaccination efforts were launched by the United States authorities and resulted in a dramatic reduction in the incidence of smallpox to some 700 cases in 1914. Because of its contacts with the USA, which had succeeded Spain as the occupying power between 1898 and 1918, the Philippines experienced what was probably variola minor (described locally as "varioid") during the second decade of the 20th century (McVail, 1923), but it was always rare, according to reported figures, compared with variola major.

Control efforts were relaxed after the transfer of responsibility for health matters from the United States to the Philippine authorities in 1916, and a very severe epidemic occurred in 1918-1919, with over 64 000 deaths (McVail, 1923). Various inefficiencies and deceitful practices were exposed by inquiries into this disaster. Subsequently, vaccination efforts were greatly strengthened, with the result that the last cases of endemic smallpox occurred in the Philippines in 1931. Apart from a few outbreaks associated with importations—notably 282 reported cases in 1948 which persisted into 1949—the Philippines has remained free of smallpox ever since (see Table 8.10).

### Malaysia

The smallpox situation in the Federated Malay States (Malaysia) before the Second World War was rather similar to that in Indonesia, the endemic disease being eliminated in the late 1930s (see Table 8.10). No figures are available for the war years (1942-1945) but by 1946 smallpox was well established again, with 3364 reported cases that year and over 4500 (1008 deaths) in 1947. The disease was rapidly curbed by control measures, and no endemic cases were reported after 1949, except for an outbreak of 338 cases in 1959 which extended into 1960, following an importation.

### Burma

Burma was administered as part of British India until 1937, and gained its independence in 1948. As in India, smallpox was a traditionally important endemic disease, usually causing between 1000 and 8000 reported deaths per year, during the period 1905-1927

(Low, 1918; see Table 8.10) in a population that rose over this period from 8.5 to more than 13 million. The incidence continued to be high, especially in the provinces, but the seaports remained reasonably free of the disease, although there was a major epidemic in Rangoon in 1950 (Murray, 1951). By 1958 the annual incidence of reported cases was still over 1000. Control measures were gradually improved and the incidence fell to some hundreds of reported cases annually by 1960; the endemic disease was eliminated in 1965. The Chinese experience of importations across the border into Yunnan Province in 1960 (see Chapter 27) suggests that there was a good deal of unreported smallpox in the remote border regions of Burma.

### Thailand

Thailand was one of the few Asian countries never to be colonized by a European power. In the early years of the century even the registration of deaths was limited to Bangkok, in which there was a very severe epidemic of smallpox in 1911-1912, with 2368 deaths in a population of about 600 000. In 1914, following this outbreak, vaccination was made compulsory, first in Bangkok and ultimately in the country as a whole. Prior to the outbreak of the Second World War smallpox appeared to be coming under control (see Table 8.10), but a rising incidence in 1944 was followed by severe epidemics in 1945 and 1946, with over 62 000 reported cases and 15 000 reported deaths. An intensive vaccination campaign brought the disease under control by the early 1950s, but there was a further outbreak, with over 1500 reported cases, in 1959, before the disease was eliminated in 1962.

### Indochina

The present-day states of Democratic Kampuchea, Lao People's Democratic Republic and Viet Nam, which before 1954 constituted French Indochina, had long suffered from endemic variola major. Reporting was very incomplete, but there was an increased prevalence during the latter years of the First World War, said to have been due to the discontinuance of official vaccination tours by government medical officers. Smallpox continued to be endemic between the wars, increasing somewhat (but not as much

as in Thailand) just after the Second World War. Major efforts at control instituted by the newly independent countries achieved elimination in the late 1950s (Lao People's Democratic Republic, 1953; Democratic Kampuchea, 1959; and Viet Nam, 1959), which was fortunate, otherwise there might have been further outbreaks during the Viet Nam conflict of 1965-1975. However, no cases were reported then by either of the warring sides.

### THE INDIAN SUBCONTINENT AND AFGHANISTAN

During the early years of the 20th century smallpox was endemic in all countries of southern Asia, and India had already emerged as the major focus of smallpox in the world, a position it retained until the disease was eradicated there in 1975. Smallpox remained endemic in all the countries of the Indian subcontinent except Sri Lanka (in which eradication was achieved in 1951) throughout the period under review (Table 8.17).

#### India

As vaccination coverage improved in British India the rate of reported deaths from smallpox gradually fell from over 2000 per million population in 1870 to less than 300 per million in 1930 (see Chapter 5, Fig. 5.2). A pattern of epidemics every 5-7 years was maintained, and even in non-epidemic years the disease caused many deaths and sometimes great disruption. For example, in 1930 smallpox afflicted all the port cities of India and in consequence other countries imposed severe restrictions on Indian shipping.

Although a Vaccination Act required that all children should be vaccinated within 6 months of birth, this was not enforced; indeed, it was not considered practicable to enforce compulsory vaccination in India. Since most older persons were immune on account of vaccination or a previous attack, smallpox was primarily a disease of children, with a very high mortality among those aged less than 1 year. By 1941 primary vaccination was legally compulsory in some 80% of towns and 60% of the villages in British India, but revaccination was compulsory only in Madras. However, by 1944 some 60 million vaccinations were being given annually in a population of about 332 million, using liquid vaccine produced in 14 laboratories situated in the different states.

In 1947 India obtained independence and the partition of British India into Pakistan (East and West) and India occurred, with the consequent readjustment of populations and reporting arrangements (Table 8.17). Large-scale vaccination continued, but many of the vaccinations were probably ineffective owing to the lack of potency and heat stability of the vaccine. However, because vaccination was readily available and variolation was legally forbidden, the latter practice ceased and was never a problem in India during the Intensified Smallpox Eradication Programme. There was little change in the situation until after 1962, when a national smallpox eradication programme was launched (see Chapter 15). Smallpox was not finally eliminated from India until May 1975.

#### Pakistan and Bangladesh

The situation was little different in India's neighbours, Pakistan and Bangladesh (East Pakistan until December 1971). Prior to partition in 1947 they had been part of British India, and a gradual increase in vaccination coverage had lowered the incidence of smallpox. In West Pakistan (Pakistan after December 1971) variolation was widely accepted as a control measure practised by Muslim religious leaders, and it continued to be used long after vaccination was introduced as a public health measure in 1875. After 1947 the Vaccine Institute in Lahore continued to prepare glycerolated liquid vaccine, but in spite of some 15 million reported vaccinations a year in West Pakistan (population in 1950, 40 million) endemic smallpox continued, especially in the cities and mainly in unvaccinated children. A variety of factors contributed to the failure of vaccination: substandard vaccine, inadequate motivation of the public, defective legislation, and lack of supervision of vaccinators. Eventually, after intensification of the national eradication programmes and help from the World Health Organization, the last case of smallpox was reported in October 1974.

There were large outbreaks in East Pakistan (Bangladesh) after partition, with 70 000 reported cases in 1950-1952 and over 100 000 cases in 1957-1958. In 1953 vaccine began to be produced by the Institute of Public Health in Dhaka. After 1958 only freeze-dried vaccine was produced, but until 1966 its quality was inferior. Smallpox was finally eliminated in October 1975.

<sup>a</sup> .. = data not recorded.<sup>b</sup> Excluding Burma; see Table 8.10.<sup>c</sup> Figures in italics denote the number of reported deaths from smallpox.<sup>d</sup> The last probable occurrence of endemic smallpox.

### Afghanistan

Afghanistan was internationally recognized as an independent state in 1921. In this rugged and sparsely populated country, smallpox remained endemic throughout the first half of the 20th century and variolation was

extensively practised (see Chapter 14). In the 1930s, Berke (1956) set up the first modern-type vaccination service, and it was reported that about 3 million persons were vaccinated in the period 1936-1939. Vaccination was made compulsory in Afghanistan in 1959.

No information is available on the smallpox incidence prior to 1949. Thereafter, the number of reported cases varied between a few hundred and about 2000 annually, mostly in the towns. The incidence of smallpox in the large population of nomads and semi-nomads was unknown. Endemic transmission ceased in 1972.

### Sri Lanka

Smallpox was much more readily controlled on the island of Ceylon (Sri Lanka) than on the adjoining mainland of India. Vigorous vaccination campaigns in the 1920s reduced smallpox to occasional outbreaks following importations from India; only 103 cases were reported between 1927 and 1931 (Table 8.17). Following another importation from India in November 1932 there was a larger outbreak, which extended into 1933, but this was followed by 5 years of virtual absence of the disease (1936-1940). As occurred elsewhere in Asia, there was a resurgence during the Second World War but control was re-established in 1947 and the elimination of endemic smallpox was claimed in 1951. Thereafter, importations from India caused small, readily controlled outbreaks in most years.

### SOUTH-WESTERN ASIA

Prior to the First World War this region consisted of the Ottoman Empire and Persia. Smallpox was endemic and largely unreported in both areas. The holy cities of Mecca and Medina provided major foci for importations and subsequent exportations of smallpox to all parts of the Muslim world. With regard to Persia the statement was made at a meeting of the Teheran International Sanitary Council in 1907 that between 50 000 and 100 000 persons died annually from smallpox (Low, 1918).

Between the First and Second World Wars the reported incidence of smallpox fluctuated in Persia and the new states that arose out of the Ottoman Empire (Fig. 8.11), but had fallen to a low level in most countries of the area by the late 1930s (Table 8.18). An epidemic focus developed in Iraq in 1940-1941, with over 3000 reported cases, and in 1942 spread westwards into Syria, Lebanon, Turkey, Palestine and Jordan and eastwards into Iran. In 1943 there was a major outbreak in Turkey which extended into Greece (see Table 8.2). Intensive vaccination campaigns were instituted in Turkey and the endemic disease was eliminated by 1951, but substantial numbers of cases continued to be reported from Iran and Iraq until the late 1950s.

### The Incidence of Smallpox on Islands

Island countries with sparse populations were spared endemic smallpox because their populations were too small to sustain continuous transmission, and they were much less frequently subject to importations than were countries of a similar size and population located on the continental mainland. The outstanding examples are Australia and New Zealand, both of which were colonized by British settlers after the concept of quarantine was established, and were so distant from smallpox-endemic countries that persons incubating the disease on embarkation were sick on arrival and were discovered during quarantine inspections. Other examples mentioned in this chapter are Sri Lanka and Madagascar, in each of which importations were less frequent and more easily controlled than in countries with comparable populations on the adjacent continents, such as Nepal and Mozambique. Locally produced liquid vaccine was more likely to be potent when administered than in continental countries, because of the short distances and, therefore, speedier delivery from production centres to villages. Very remote islands were either spared the disease entirely or subject to widely spaced devastating epidemics such as occurred in Iceland before 1870. If the population of the island was dense enough, however, as in Java, endemic smallpox could be firmly established and proved difficult to eliminate.

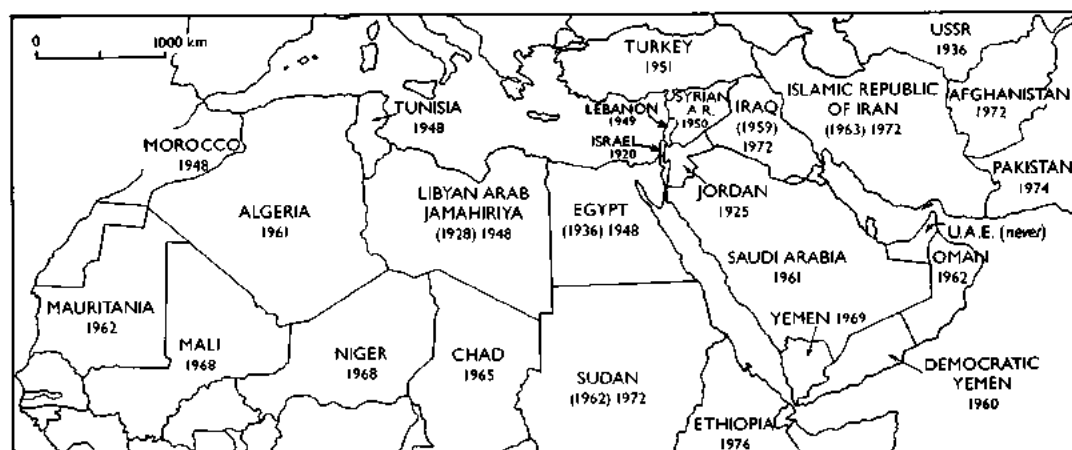

Fig. 8.11. North Africa and south-western Asia: year in which smallpox ceased to be endemic in each country (national boundaries as of 1982). Dates in parentheses (for Algeria, Egypt, Iraq, Islamic Republic of Iran, Libyan Arab Jamahiriya and Sudan) indicate the initial elimination of endemic smallpox, after which endemicity was again established before final elimination in the year shown.

and early 1960s. Endemic smallpox was re-established in Iran, Iraq and the Syrian Arab Republic in 1971-1972, but then brought under control (see Chapter 23).

### SMALLPOX IN AFRICA, 1900-1958

Although smallpox arrived in some countries in central Africa as late as the 19th century (see Chapter 5), the disease was firmly entrenched throughout the continent during

the first quarter of the 20th century. Variola major predominated in most places, but variola minor occurred concurrently in many countries in southern and eastern Africa. Vaccination was practised less than variolation, but both were uncommon. Tulloch (1980) reviewed the incidence of smallpox in different countries in Africa over the half-century between 1928 and 1977; the changes in incidence over the 3 decades 1938-1967 are illustrated in Fig. 8.12. The continued endemicity of smallpox in all countries of Africa

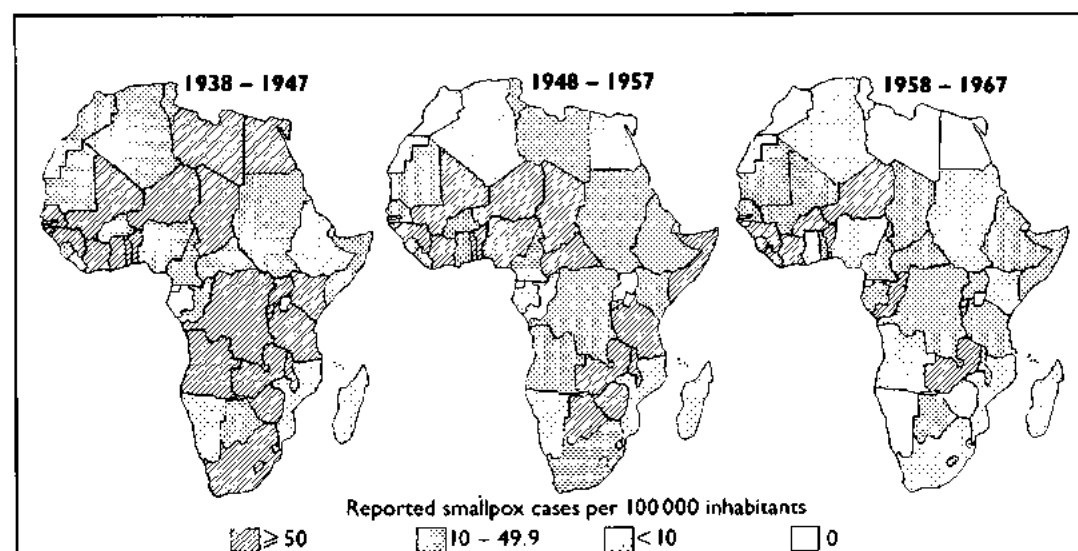

Fig. 8.12. Africa: maximum reported annual incidence rates of smallpox during each decade, 1938-1967. No data available for Equatorial Guinea, 1938-1947. (From Tulloch, 1980.)

during the period under review (Fig. 8.13), except those of the Mediterranean littoral (Fig. 8.11), is evident.

There is no generally accepted way of subdividing this large and varied continent. The descriptions of the eradication programmes in Africa follow one pattern (Chapters 17-22) and those of certification by the international commissions follow another (Chapters 25-27). The countries of the Mediterranean littoral constitute a well-defined North Africa (Fig. 8.11); while the countries south of and including Angola, Zambia,

Malawi and Mozambique clearly delimit southern Africa (Fig. 8.15). The countries between these two regions have been designated as western, central and eastern Africa (Fig. 8.14).

## NORTH AFRICA

The countries of the Mediterranean littoral of Africa (see Fig. 8.11) have long had more extensive contacts with other Mediterranean countries than with Africa south of the

Fig. 8.13. Number of countries of the 47 in Africa in which smallpox was endemic at various times between 1920 and 1977. National boundaries as of 1982.

Sahara. Smallpox was endemic in all these countries in the first 4 decades of the century (Table 8.19). In Egypt, the most populous country of the region, smallpox was endemic but epidemics in which 2 or 3 times the usual incidence was reported occurred in 1904-1905, 1909, 1914-1915 and 1919-1920 (Table 8.20). General vaccination of the whole population was carried out in 1919 and again in 1926 in response to an epidemic that took place during that year (Ahmad, 1933). Smallpox was also reported to be very common in Algeria, Morocco, and Tunisia; Low (1918) quotes Clemow as stating that variolation by insufflation was practised in Tunisia, "often with disastrous results".

By the mid-1930s vaccination campaigns organized by the various colonial powers in the region—France, Italy, Spain and the United Kingdom—had reduced smallpox to low levels (Table 8.19). There was a severe epidemic in Egypt in 1932-1934, which did not affect the other North African countries. At the end of the 1930s endemic smallpox had been virtually eliminated in all these countries except Morocco, but the fighting and unrest associated with the Second World War led to severe outbreaks in all 5 countries, including the sparsely populated Libya. The contrast with Europe is striking (compare Tables 8.1 and 8.19); the only outbreak of smallpox in Europe associated with the Second World War (Italy, 1944-1947) was due to an importation from North Africa, whereas major epidemics occurred over a period of several years in each of the North African

countries. Most of these were due to variola major, but the outbreaks in Morocco were apparently caused by variola minor (case-fatality rates, 2-3%). However, after 1948, improved health services brought about a great reduction and the eventual elimination of smallpox throughout North Africa—more slowly in Algeria, which was engaged in internal conflict, than elsewhere. This was accomplished by vaccination campaigns utilizing liquid vaccines.

### WESTERN, CENTRAL AND EASTERN AFRICA

These regions comprise a large area lying between latitudes 22°N and 12°S, and include some 30 countries (Fig. 8.14). During the first part of the 20th century most of these countries were administered as colonies, by several European powers—Belgium, France, Germany (until the First World War) and the United Kingdom. They became independent countries mostly during the late 1950s and early 1960s. Smallpox was endemic in the majority of them throughout the 1960s and in Ethiopia and Somalia until the mid-1970s.

#### Western Africa

The reported incidence of smallpox in selected countries of this region is shown in Table 8.21. Reporting was unsatisfactory except in the major towns, but there did not seem to have been much diminution in the incidence of smallpox during the 20th century up to the time of independence, except in some of the French colonies.

More detailed accounts exist of the severity of smallpox in particular colonies and countries. Külz (1905) suggested that at the beginning of the 20th century the annual mortality from smallpox in Togoland (then a German colony) amounted to as much as 1% of the population.

The situation in French West Africa has been described by Breman et al. (1977a). The Federation of French West Africa was formed in 1904, and shortly after this the French authorities reported smallpox in several territories of the Federation. A vaccine production centre was established at Kindia in Guinea in 1905, and from 1909 onwards a more stable dried vaccine was used (Fasquelle & Fasquelle, 1971). As surveillance improved the completeness of reporting increased; case-fatality

<sup>a</sup> A horizontal line beneath a figure indicates that this represents the last probable occurrence of endemic smallpox.<sup>b</sup> .. = data not recorded.

rates in French West Africa as a whole varied between 6% and 20%. Variola minor appears to have occurred without concurrent variola major in Guinea in 1939 and 1940, and again in 1959-1961. Otherwise the data suggest that both variola major and variola minor occurred at some time each year in some part of the Federation.

Fasquelle & Fasquelle (1971) have described the eradication programme that was mounted in Côte d'Ivoire in 1961, the year

after it became independent. The objective was achieved by mass vaccination, using French-type freeze-dried vaccine. In a population of 3.8 million, 2.4 million vaccinations were carried out in 1961 and 3.7 million by 1963. The routine was established of primary vaccination during the first year of life and revaccination at school age and again at the age of about 18 years. The incidence of smallpox fell rapidly, elimination being achieved in 1966.

<sup>a</sup> Based on Ahmad (1933).<sup>b</sup> In 1890 a law was introduced requiring the vaccination of every newborn infant before the age of 3 months. It was amended in 1897 and 1917, but not enforced.<sup>c</sup> General vaccination of the whole population (i.e., vaccination and revaccination) was carried out in these years.

### Central Africa

The countries included in this somewhat arbitrary grouping are Burundi, the Central African Republic, Chad, Rwanda, the Sudan, Uganda and Zaire. The incidence of smallpox in the most heavily populated of these countries during the period 1920-1966 is shown in Table 8.22. The Sudan and Zaire are the two largest countries in Africa and have strongly contrasting climates, much of the Sudan

being semi-desert, while Zaire includes the largest area of tropical rain forest in Africa. The Sudan was under Anglo-Egyptian control until 1955 and became completely independent in 1956. Zaire was a Belgian colony from 1908 until 1960, when it gained independence and became the Democratic Republic of the Congo, changing its name to Zaire in 1971.

### Sudan

The smallpox situation in the Sudan has been described in some detail by Bayoumi (1974) and Hartwig (1981). The largest country in Africa, the Sudan was located at a major crossroads for smallpox transmission, being continually exposed to the introduction of smallpox from Egypt by way of the traffic on the Nile, from West Africa through groups of pilgrims crossing the country to and from Mecca (Bayoumi, 1972), and from Ethiopia in the east.

Records of reported cases of smallpox go back to 1925 (Bayoumi, 1974; see Table 8.22), all parts of the country being affected. Variola minor was endemic in the south and east, where the Sudan borders on Zaire, Uganda and Ethiopia, and there were repeated importations of variola major from the west, brought in by the large numbers of pilgrims and immigrants from western Africa and other central African countries. From time to time these produced sporadic outbreaks, mainly during the dry season, when maximum population movement usually occurred.

There was a severe epidemic of variola major extending from 1927 until 1931, apparently introduced by Ethiopian migrants. An extensive outbreak of variola minor occurred in the south between 1932 and 1934, but this did not cause nearly as much concern to medical administrators as did the periodic outbreaks of variola major along the pilgrim route and in the Gezira Irrigation Scheme (Bayoumi, 1974). Extensive vaccination campaigns, performed almost yearly in one or more provinces, reduced the incidence, and from 1941 to 1946 the reported incidence was under 250 cases a year. In 1947, scattered epidemics developed and continued until the end of the 1940s along the major lines of communication in Kordofan, Blue Nile and Kassala provinces, predominantly of variola minor, but with sporadic outbreaks of variola major. The incidence declined substantially in the mid-1950s, although there was a serious

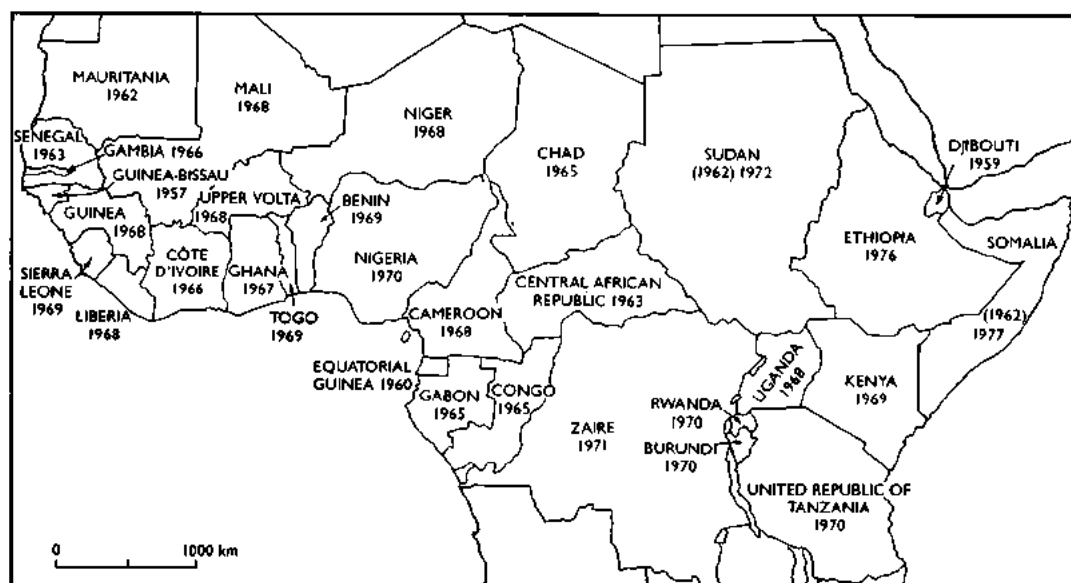

Fig. 8.14. Western, central and eastern Africa: year in which smallpox ceased to be endemic in each country (national boundaries as of 1982). Dates in parentheses (for Somalia and Sudan) indicate the initial elimination of endemic smallpox, after which endemicity was again established before final elimination in the year shown.

outbreak in Equatoria Province in 1954, and outbreaks which were probably still occurring among nomads and pilgrims were rarely reported. Endemic smallpox was eliminated in 1962, but was re-established in 1967 and eventually eliminated again in 1972 (see Chapter 18).

#### *Zaire*

Data on cases and deaths in the former Belgian Congo from about 1940 onwards suggest that during the 1940s variola minor was the predominant variety of smallpox in that country, and the same situation obtained

### **The Sudan and the Pilgrimage to Mecca**

The Mecca Pilgrimage is probably the largest of all pilgrimages to a sacred place, and currently involves over a million pilgrims assembling at the holy places in Saudi Arabia over a period of a few days, at a fixed date in the Hegira year. The Sudan, of which the northern and central parts are inhabited by Muslims, is at the crossroads of the passage of pilgrims from the large Islamic populations in western Africa to Mecca. They came, and come, by all kinds of transportation from western Africa through Chad to cross the ill-defined border of some 900 kilometres into the provinces of Darfur and Kordofan. Within the Sudan, they often stop to work in the Gezira, and then go on by road or railway to Port Sudan, whence they cross the Red Sea by boat to Saudi Arabia. In the 1920s a quarantine station was established at Geneina, on the Sudan-Chad border, but many pilgrims evaded it. Outbreaks of variola major in northern Sudan in 1927, 1929, 1949, 1951-1952 and 1952-1953 were attributed to entries by this route, and the disease subsequently moved westwards along the pilgrim route (Bayoumi, 1972). Later, more elaborate precautions were taken in Saudi Arabia to control the entry and dissemination of disease by pilgrims coming from all parts of the world (see Chapter 27).

in the former trust territory of Ruanda-Urundi (now Rwanda and Burundi). However, in most years outbreaks of variola major and variola minor occurred, usually in different parts of the area. After 1960 variola major appeared to predominate (see Chapter 18). Liquid glycerolated vaccine was prepared in the colony's own laboratories, but the Belgian authorities reported great difficulties in dis-

tributing potent vaccine. The take rate in primary vaccinations during 1938-1946 varied between 8.8% and 74.3%, with an average for the 9 years of 37.6% (Tulloch, 1980). Many cases of smallpox, including variola minor, were reported in subjects who were supposed to have been vaccinated (Fabre, 1948). Endemic smallpox was not eliminated until 1971.

<sup>a</sup> A horizontal line beneath a figure indicates that this represents the last probable occurrence of endemic smallpox.<sup>b</sup> .. = data not recorded.<sup>c</sup> From 1962, the two separate states of Rwanda and Burundi.

### Uganda

Prior to the First World War, the main sources of smallpox were the caravans of Arab and other traders. Between 1914 and 1920 over 20 000 deaths from smallpox were reported in Uganda, the overall case-fatality rate among cases treated in government hospitals between 1911 and 1923 being over

23%. Following extensive vaccination, only a few outbreaks were reported between 1920 and 1944, when the outbreak of variola minor that had started in Kenya in 1943 spread to Uganda, producing 4737 reported cases in 1944, and then gradually declined. Small outbreaks, one of which, in 1956, was due to variola major, continued every year until endemic transmission ceased in 1968.

### Eastern Africa

This grouping of countries includes Ethiopia, Kenya, Somalia and the United Republic of Tanzania, former colonies of European powers which became independent in the 1950s and early 1960s. Smallpox appears to have been common in the early part of the 20th century and case-fatality rates were usually between 20% and 30% (Low, 1918). Table 8.23 sets out the reported annual

incidence of smallpox in these countries from 1920 to 1966. As elsewhere in Africa, the figures provide an index of the incidence but it is certain that there was gross under-reporting.

#### Ethiopia and Somalia

It is difficult to obtain reliable information on smallpox in Ethiopia before the Intensi-

<sup>a</sup> .. = data not recorded; + = smallpox present, but number of cases unknown.

<sup>b</sup> In 1964, combined with Zanzibar and Pemba to form the United Republic of Tanzania.

<sup>c</sup> The last probable occurrences of endemic smallpox.

fied Smallpox Eradication Programme began work there in 1971, when only variola minor was present and was very poorly reported (see Chapter 21). Early in the century smallpox caused devastating outbreaks, and just before the First World War about 20% of the population of the province of Shewa (in which Addis Abeba is situated) were said to be pockmarked (Pankhurst, 1965). Extensive vaccination campaigns were undertaken by Italian health officials after the Italian occupation of the country in 1936, vaccine being produced in Addis Abeba. Murray (1951) was unable to comment on smallpox in Ethiopia, except to say that "a small but steady incidence" occurred in Shewa Province. Teclemariam (1965) reported that an epidemic of smallpox with a high case-fatality rate took place in the Shewa area in 1960 and a smaller outbreak occurred in 1964, but Herrlich et al. (1963) reported experiments with a strain of "alastrim virus" recovered during an epidemic in Ethiopia in 1958. Variola minor appears to have completely replaced variola major throughout Ethiopia before 1971, and was finally eliminated in 1976.

In the colonies that eventually became Somalia, Low (1918) reported that epidemics of variola major occurred in the early years of the century, mainly in the larger towns when fairs were held. By the late 1940s endemic smallpox had been eliminated from the Somaliland Protectorates, but outbreaks occurred following importations during the mid-1950s. This pattern continued, and the last major outbreak of smallpox in the world occurred in Somalia in 1976-1977, following importations from Ethiopia.

### *Kenya and the United Republic of Tanzania*

Prior to the First World War the prevalence of smallpox in the two colonies of Kenya and Tanganyika was lower than in the 19th century. Vaccination was introduced in the larger towns, but outbreaks of variola major, with case-fatality rates of 25-30%, occurred sporadically. From the mid-1930s onwards variola minor occurred from time to time and because it was so much milder than variola major proved considerably more difficult to control (Conacher, 1957).

The situation in Kenya has been documented somewhat more fully than in many other African countries, but is characteristic of the situation in a large number of them. There was a severe famine in central Kenya in 1897-1900, due to a combination of drought, pleuropneumonia and rinderpest among the cattle, and a locust plague. Dawson (1979) has drawn attention to the way in which extensive movements of the population in quest of food created the conditions for the severe outbreak of smallpox that occurred in 1899. Subsequently, the social changes accompanying European colonization changed the pattern of smallpox in Kenya, as in other African colonies.

The production of smallpox vaccine, using seed virus obtained from India, began in Nairobi in the first decade of the century. Trade expanded with the introduction of cash crops, labour migration caused larger and more frequent population movements and urbanization created larger and denser populations—all of which increased the opportunities for the transmission of smallpox. On the

### **Special Relations between Eastern Africa and India**

Throughout history, Arab dhows and ships from India have traded with the ports on the east coast of Africa. During the early days of British colonization in Africa indentured labourers were brought from India to assist in large-scale agricultural production in Natal (South Africa), Kenya, Uganda and Tanganyika. The Indian indentured labourers soon established themselves as shopkeepers throughout these colonies and active communications were maintained between them and their relatives in India. This traffic had a significant influence on the incidence of smallpox in eastern Africa, especially in Kenya and Tanganyika, and to a lesser extent in Natal, variola major ("Asiatic smallpox") being repeatedly imported into all three areas from India.

other hand, vaccination, though ineffective as a general public health measure because of poor vaccine and inadequate funding, was used effectively to control outbreaks of variola major, so that smallpox appeared in frequent local outbreaks with very occasional widespread epidemics. A notable example of the latter occurred in 1916, when survivors of the Carrier Corps (a contingent of Kenyan Africans who acted as army porters during the British invasion and conquest of German East Africa (Tanganyika)) were returned from Nairobi to their home districts regardless of their medical condition. The result in one province, repeated in many others, was 100 separate outbreaks of smallpox, as well as other diseases (Dawson, 1979).

The production of vaccine in Nairobi was greatly expanded in the 1930s to supply most of the British colonies in eastern Africa. Variola major was imported into Mombasa from India on several occasions during the 1920s and 1930s, but endemic smallpox was eliminated from Kenya in 1930. In 1934 variola major was introduced again from the north, by nomadic Somalis (Seymour-Price et al., 1960). A widespread epidemic occurred but the disease was eliminated in 1936, only to be reintroduced by refugees from Ethiopia in 1937. No cases were reported in 1938-1942. In 1943 an epidemic of variola minor occurred, to be followed by an explosive epidemic of variola major in 1945. Subsequently, variola minor continued at a low level throughout the early 1950s, but it spread widely during the disturbances associated with Kenya's struggle for independence in 1956-1958.

Smallpox was eventually eliminated from Kenya in 1969 and from the United Republic of Tanzania in 1970.

### SOUTHERN AFRICA

The countries included in this region are shown in Fig. 8.15. Table 8.24 sets out the reported incidence of smallpox in each of them between 1920 and 1966.

#### Angola and Mozambique

These former Portuguese territories, on the Atlantic and Indian Ocean shores of southern Africa, became independent in 1975. In relation to their experience of smallpox, they

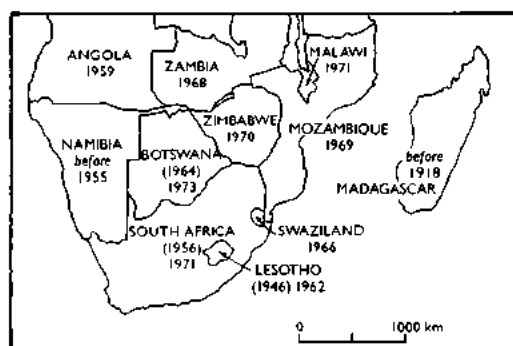

Fig. 8.15. Southern Africa: year in which smallpox ceased to be endemic in each country (national boundaries as of 1982.) The dates in parentheses (for Botswana, Lesotho and South Africa) indicate the initial elimination of endemic smallpox, after which endemicity was again established before final elimination in the year shown.

had more in common with each other than with neighbouring British colonies. Both variola major and variola minor were present during the 1940s, but the latter eventually predominated. The Portuguese promoted vigorous vaccination campaigns, using locally produced vaccines, and had eliminated smallpox from Angola by 1959, and from Mozambique by 1969.

#### Malawi, Zambia and Zimbabwe

These three former British colonies had rather similar histories, typified by Zambia, in which the picture between 1920 and 1950 was one of a reduction in the incidence of variola major in the late 1930s, followed by sporadic cases of variola minor in 1940-1943, rising to a major epidemic of 6354 cases with 28 deaths in 1945. The incidence of variola minor then declined, but there was an outbreak of variola major in the Zambesi valley in 1948, with 671 reported cases and 212 deaths. Very few cases were recorded in 1949-1951, but the incidence then increased, and there was an epidemic with over 3500 reported cases in 1955. Both varieties of smallpox persisted until the disease was eliminated in 1968.

#### South Africa and Adjacent Countries

South Africa, the two small enclaves of Lesotho and Swaziland, and neighbouring Botswana and Namibia (formerly (German)

<sup>a</sup> .. = data not recorded.<sup>b</sup> A horizontal line beneath a figure indicates that this represents the last probable occurrence of endemic smallpox.<sup>c</sup> Endemic smallpox was eliminated during the First World War.

South West Africa) had similar experiences of smallpox, modified in each by population density, as well as the volume of international traffic—and thus the risk of importations—from other parts of Africa and from the Indian subcontinent.

The situation can be exemplified by South Africa, through which severe epidemics of variola major swept in the 18th and 19th centuries, usually after importations from

India into Cape Town. After the last large epidemic in 1881, vaccination was made compulsory in the Cape Colony, a law which was extended throughout the Union of South Africa in 1919. Since the latter part of the 19th century it had been recognized that in addition to this severe disease, against which vigorous action was taken by the public health authorities, there was endemic among the black population a very mild form of

smallpox, "amaas", which today is classified as *variola minor*. From the turn of the century onwards, *variola minor* persisted in South Africa as an endemic disease, which was greatly underreported. Superimposed on this background, outbreaks of *variola major* occurred from time to time, especially during the First and Second World Wars.

Immediately after the First World War, an epidemic of *variola minor* occurred (over 1000 reported cases in both 1920 and 1921); then the reported morbidity fell to very low levels between 1927 and 1936. After that smallpox became more frequent, especially in the Transvaal, and in 1940 and 1941 epidemics of *variola minor* occurred in several places, probably because of the movement of the black population in connection with wartime activities. In 1943, *variola major* occurred in Natal, probably after an importation via a mule ship returning from India, and spread throughout that province and into the Transvaal. Whites as well as blacks were affected and the case-fatality rate was high (30% in 1945), although the case-fatality rate pertaining to both forms of smallpox for that year was only 5%. Vaccination was made compulsory, a vigorous vaccination campaign was launched and the epidemic came to an end in 1947. The annual case-fatality rates observed thereafter in different provinces, which were often between 4% and 10%, were usually calculated from a combination of cases and deaths due to both varieties of smallpox; sometimes there were "pure" epidemics of *variola major*, with case-fatality rates of 39% (Natal, 1951), 23% (Transvaal, 1952) and 20% (Cape Province, 1964). Only 2 deaths were recorded among the 948 cases of smallpox reported between 1965 and 1971, when the last endemic case was notified.

### Madagascar

The main point in including Madagascar in this historical survey is to emphasize the relative ease with which smallpox was controlled on an island off the coast of Africa, compared with the problem in countries of similar size and with comparable health services on the mainland. According to Coulanges (1977) *variola major* was once endemic in Madagascar and periodically there were severe epidemics from infection introduced from Africa or India, as in 1901, when 262 cases (with 98 deaths) were reported. Vaccine

production was begun in Antananarivo in 1899 and compulsory vaccination and revaccination were instituted in 1909. Favoured by its geographical isolation, Madagascar was the first country in Africa to eliminate smallpox. This was achieved during the First World War, after which there were no further cases of smallpox in Madagascar, except for a few imported cases each year between 1925 and 1931.

### SMALLPOX IN OCEANIA DURING THE 20TH CENTURY

Apart from some widespread outbreaks among the aborigines of Australia during the 19th century, all of which died out after a few years (see Chapter 5), smallpox never became established as an endemic disease in Australia, New Zealand or the islands of the Pacific Ocean. From the beginning of the 20th century they were well protected from importations by their geographical remoteness and the effective quarantine measures imposed on visiting shipping. This situation led to a disregard for infantile vaccination, which by the early years of the 20th century had reached a very low level in Australia and New Zealand.

Nevertheless, a long-standing requirement for valid vaccination certificates for all travellers, combined with vigilant seaport and, later, airport medical inspections and quarantine, kept both Australia and New Zealand free of serious outbreaks of smallpox, except for separate importations of *alastrim* into each country in 1913.

### Australia

The Australian epidemic of *alastrim* was initiated in April 1913 by a ship's steward who was infected in Vancouver, Canada, and slipped through the medical inspection in Sydney (Cumpston & McCallum, 1925). The outbreak which followed lasted until December 1917 and produced 2400 cases in various parts of Sydney and in country towns in New South Wales, but only a minor extension into one other state—Queensland. It was of very low virulence, with only 2 deaths attributable to smallpox, and of low infectivity, spreading slowly in a largely unvaccinated population of 1.8 million. Control was achieved by vaccination and the segregation of cases and contacts. Subsequently a few very small outbreaks

of both variola major and variola minor occurred, but the effectiveness of the quarantine arrangements was indicated by the fact that, between 1909 and 1923, 40 ships were quarantined for smallpox or suspected smallpox.

### New Zealand

The New Zealand epidemic was introduced by a Mormon missionary in April 1913 and lasted about a year. Among people of European origin, there were 114 reported

cases, with no deaths, but among the Maoris—the indigenous Polynesian people—there were 1778 reported cases and 55 deaths. Although cases among the Maoris were probably underreported, Dixon (1962) noted that some cases of variola minor were very severe in this population group, which had never before been exposed to smallpox.

### Hawaii

Situated at the crossroads of the Pacific, Hawaii was frequently visited by ships with

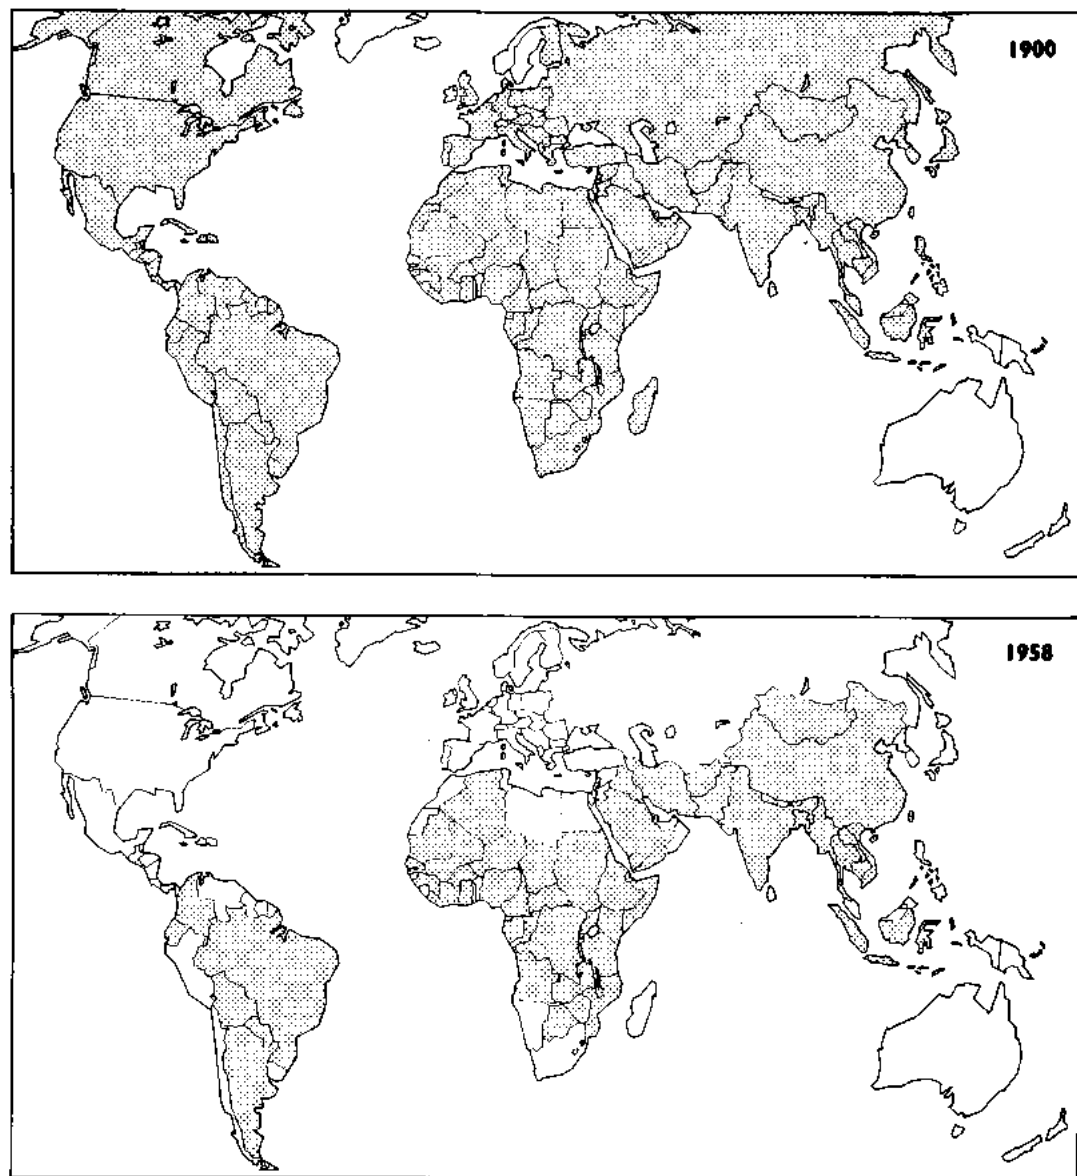

Fig. 8.16. Countries in which smallpox was endemic in 1900 and in 1958.

smallpox patients on board, especially during the early years of the century. For example, there were 5 cases on 4 ships in 1903, 3 cases on 1 ship in 1906, 8 cases on 1 ship in 1907, 5 cases on 3 ships in 1908 and 16 cases on 8 ships in 1910. Most of these ships came from ports in eastern Asia, but occasionally a ship from San Francisco carried a patient with variola minor, which, however, never became established on the islands. The only outbreak to occur on land during the 20th century was in the detention camp to which illegal immigrants from the Philippines were taken, and in which there were 52 cases of variola major in 1911.

#### **SUMMARY: THE GLOBAL INCIDENCE OF SMALLPOX, 1900-1958**

At the beginning of the 20th century—about a hundred years after the introduction of vaccination—smallpox was still endemic in almost every country of the world (Fig. 8.16). A few countries in Europe with small populations had eliminated the disease by vaccination, and the isolated and sparsely populated countries of Australia, New Zealand and many small islands were protected by distance and effective seaport medical inspections and quarantine.

The only variety of smallpox found in Asia was variola major, but for the first two or three decades of the 20th century endemic variola major and variola minor coexisted in many countries of Africa and North and South America, as well as in a few countries of

Europe. By the 1930s variola major had been completely replaced by variola minor as an endemic disease in the USA, Canada, the United Kingdom and in several Latin American countries, but curiously not in Mexico.

In Europe, the reductions in the incidence of smallpox achieved early in the 20th century were reversed by the First World War (1914-1918), which led to a great resurgence of the disease in Russia and its spread from there to many other countries. Between the First and Second World Wars it was gradually brought under control in Europe and North America and in a few countries elsewhere but continued almost unchecked in Africa and most of Asia, where any gains made were lost during and just after the Second World War. This latter conflict had virtually no influence on the incidence of smallpox in Europe and North America.

After the Second World War data collection by the World Health Organization gave a better picture of the global scene. Both Europe and North America were free of endemic smallpox in 1958 (Fig. 8.16). Significant advances were also made in some countries of Asia and in Central and South America. During the 1950s smallpox was eliminated from most countries of the Mediterranean littoral of Africa. Elsewhere in Africa it remained endemic—variola major in some places, variola minor in others, and both concurrently in many countries. Smallpox was eliminated from China and several other countries of eastern Asia during the 1960s, but on the Indian subcontinent variola major remained a widespread and severe endemic disease.

### THE COMMITMENT TO GLOBAL SMALLPOX ERADICATION, 1958-1959

The decision by the Twelfth World Health Assembly, in May 1959, to undertake the global eradication of smallpox marked the beginning of a programme which, some 18 years later, would witness the last naturally occurring case. The Health Assembly's policy, which made the global eradication of a disease one of WHO's goals, was not without precedent, a similar decision with regard to malaria having been taken 4 years before.

The commitment to smallpox eradication in 1959 represented, for the Health Assembly, an abrupt reversal of its views regarding the disease. The problem of smallpox and its control had been the subject of discussions in the Health Assembly in 1950, 1953, 1954 and 1955. An eradication programme had been proposed, in fact, by the first Director-General, Dr Brock Chisholm, to the Sixth World Health Assembly in 1953. However, after 2 years of study and debate, the Eighth World Health Assembly, in May 1955, rejected the concept as unrealistic, and the terse resolution which was adopted (WHA8.38) simply urged "that health administrations conduct, wherever necessary, campaigns against smallpox as an integral part of their public-health programmes" (World Health Organization, 1973a).

From 1955 to 1958, the issue of smallpox eradication lay dormant but, at the Eleventh World Health Assembly, Professor Viktor Zhdanov, Deputy Minister of Health of the USSR and a delegate to the Health Assembly, presented a formal, lengthy report which argued that the problem of smallpox was an important one for endemic and non-endemic countries alike, that eradication was theoretically feasible and that national programmes had demonstrated it to be a practicable possibility (World Health Organization, 1958a). The report concluded: "As regards its

complete eradication throughout the world, we think that this can be achieved within the next ten years." No reference was made to an 8-year-old regional programme for smallpox eradication in the Americas nor to the Health Assembly's earlier discussions on smallpox. The USSR had not participated in those discussions, however, having withdrawn from active participation in WHO from 1948 to 1957.

The new initiative originated with Professor Zhdanov himself. From 1951, when he had first assumed responsibility for communicable disease control in the USSR, as Chief of the Department of Sanitary and Epidemiological Services, he had taken an active interest in the concept of disease eradication. His interest was stimulated, in part, by the successful interruption of smallpox transmission throughout the USSR in 1936, and by the elimination of dracunculiasis from the Central Asian republics of the USSR following a 10-year campaign that ended in 1932 (Isaev, 1956; Litvinov, 1970). These successes led him to initiate a study of infectious diseases in the Soviet Union for the purpose of identifying others which might similarly be eliminated (Zhdanov & Timakov, 1952). By assigning more resources in the short term to disease elimination, longer-term savings could be anticipated. Smallpox remained a problem, however, particularly in the Central Asian republics, because of importations from Afghanistan and Iran, 537 cases being recorded between 1950 and 1957 (Burgasov, 1968). Professor Zhdanov's report to the Health Assembly pointed out that the danger which endemic countries posed to others caused "the countries which are free from smallpox... to make considerable efforts and spend large sums on vaccinating and revaccinating the population in order to provide constant strong immunity against this disease". Smallpox, as he saw it, would be much easier to eradicate than any of the other infectious diseases, as indicated by the success of the

programme in the USSR. Despite the diverse problems presented by a country so large and abundantly populated, transmission had been stopped by means of a programme of compulsory vaccination (Vasil'ev & Vasil'ev, 1982). For other countries to do likewise seemed both logical and feasible and the USSR was willing to offer its assistance to support such efforts. In addition to offering 25 million doses of vaccine to WHO, it informed the Director-General at the twenty-third session of the Executive Board that it had sent offers of assistance to Burma, Cambodia (later Democratic Kampuchea), Ghana, Guinea, India, Indonesia, Iraq and Pakistan (World Health Organization, 1959a).

The Eleventh World Health Assembly was held in Minneapolis, Minnesota (USA), and, with this venue in mind, Professor Zhdanov introduced his report with a quotation: "As early as 1806, the President of the United States of America Thomas Jefferson... said in his letter to Jenner: 'It is owing to your discovery... that in the future the peoples of

the world will learn about this disgusting smallpox disease only from ancient traditions'." The Zhdanov report proposed that vaccination and revaccination campaigns should be conducted throughout the endemic areas of the world, commencing in 1959. It recommended that vaccination should be made compulsory and that freeze-dried vaccine should be used. It also suggested that the programme could be accelerated if the Leicester system were introduced as well. This system, as noted in the report, was used for outbreak control, mainly in England (see Chapter 6), and resembled what eventually came to be called surveillance-containment activities—namely, "prompt identification of the disease, special notification, isolation, quarantine, disinfection measures"—although it included the "eradication of flies" as well (Fraser, 1980).

The draft resolution introduced by the USSR in 1958 for consideration by the Health Assembly differed from the report in suggesting that eradication in 4-5 years was possible in accordance with the following timetable: (1) preparation of the necessary amount of vaccine in 1958-1960 and the training of vaccinators; (2) vaccination during 1959-1960 of the populations in which principal endemic foci existed; and (3) completion of eradication in 1961-1962 by additional vaccination and revaccination. Nothing was said of the Leicester system in the resolution.

The concept of global eradication was broadly endorsed by virtually all the delegates who spoke, although a number believed that the timetable was too optimistic and some wondered whether there might not be insuperable technical and administrative problems. Accordingly, the resolution was altered to request "the Director-General to study and report to the Executive Board... on the financial, administrative and technical implications of a programme having as its objective the eradication of smallpox" (see box).

Immediately after the Health Assembly, the Executive Board met and formally accepted the gift of freeze-dried vaccine from the USSR, as well as 2 million doses of glycerolated vaccine offered by Cuba. The Board noted in resolution EB22.R12 that the Director-General would establish a special account for smallpox eradication, which would "be credited with the value, as reported by the governments concerned, of these gifts of vaccine and of any gifts for the same purpose which may be accepted by the Board

WHO 1961

**Plate 9.1.** Viktor M. Zhdanov (b. 1914), Academician and Deputy Minister of Health of the USSR, 1955-1960, proposed to the World Health Assembly in 1958 that WHO should undertake the global eradication of smallpox. Many epidemiologists whom he trained while Director of the Ivanovsky Institute served as WHO staff and consultants for the eradication of smallpox.

**Resolution WHA11.54, adopted at the Eleventh World Health Assembly in 1958**

"Noting that smallpox still remains a very widespread and dangerous infectious disease and that in many regions of the world there exist endemic foci of this disease constituting a permanent threat of its propagation and consequently menacing the life and health of the population;

"Having regard to the economic aspect of the question, which shows that the funds devoted to the control of and vaccination against smallpox throughout the world exceed those necessary for the eradication of smallpox in its endemic foci and consequently the destruction of the sources from which the infection arises and spreads, and clearly indicates that the eradication of smallpox might in future make vaccination and all expenditures involved in its application redundant;

"Taking into account the level of development reached by medical science and the health services in the control of infectious diseases, and in particular of smallpox, and the manifest tendency of the morbidity of smallpox to diminish in recent years;

"Having regard to the decisions and pertinent practical measures adopted by WHO for smallpox control and the intensification of antismallpox programmes, in particular resolutions WHA3.18, EB11.R58, WHA6.18, EB12.R13, EB13.R3, WHA7.5, WHA8.38, and WHA9.49; and

"Considering it opportune to raise the problem of the world-wide eradication of smallpox in the near future,

"1. REQUESTS the Director-General to study and report to the Executive Board at its twenty-third session on the financial, administrative and technical implications of a programme having as its objective the eradication of smallpox, the study to include the various problems involved in carrying out the following activities:

- (a) investigation of the means of ensuring the world-wide eradication of smallpox, taking into account the fact that smallpox persists in certain areas despite repeated vaccination campaigns;
- (b) encouragement of the preparation during 1958-1960 of the necessary amount of smallpox vaccine in national laboratories and institutes;
- (c) training of vaccinators among the local population in countries in which mass immunization campaigns will be conducted;
- (d) the pooling of experience and the formulation of recommendations for the production of a sufficient amount of thermostable smallpox vaccine suitable for prolonged storage and use in tropical and subtropical regions of the world, and
- (e) study of the measures to be taken in order to avoid complications which might result from smallpox vaccination;

"2. RECOMMENDS to all governments:

- (a) that during 1959-1960 the population be vaccinated in countries in which principal endemic foci of smallpox exist; and
- (b) that during 1961-1962 additional vaccination of the population should be carried out in foci where the disease persists, and that subsequently revaccinations be given to the extent it becomes necessary in accordance with the experience acquired in each country;

"3. RECOMMENDS that all countries in which smallpox vaccination is compulsory continue to give smallpox vaccinations during the eradication of this disease throughout the world;

"4. CALLS upon medical scientists and scientific institutions active in the field of microbiology and epidemiology to stimulate their efforts towards improving the quality and the technology of the production of satisfactory smallpox vaccine resistant to the influence of temperature; and

"5. REQUESTS the Director-General to report to the Twelfth World Health Assembly on the progress made and the results obtained."

or the Health Assembly in the future" (World Health Organization, 1973a). The resolution included an important provision: "REQUESTS the Director-General to ensure, in accordance with the normal practice of the Organization, that any vaccine accepted for the anti-smallpox programme is of acceptable quality." Aware that standards for the potency and purity of vaccines of all types were not uniform throughout the world, and even nonexistent in some countries, Mr Milton P. Siegel, an Assistant Director-General of WHO, had drafted this cautionary proviso. As the Director-General noted: "... there were no international standards for vaccines. It was hoped that the Expert Committee on Biological Standardization would establish such standards soon" (World Health Organization, 1958b). This was done, in fact, in November 1958 and formalized in resolution EB23.R40 at the next session of the Executive Board (World Health Organization, 1959a). The stipulation with regard to vaccine quality was to prove most important, and after 1967 it was interpreted by WHO smallpox eradication staff as applying to all vaccines supplied to WHO-supported smallpox eradication programmes, whether or not they were provided through contributions to WHO (see Chapter 11).

The Director-General, as requested, submitted to the Executive Board in January 1959, and later to the Twelfth World Health Assembly, a lengthy report concerning the financial, administrative and technical implications of a smallpox eradication programme

(World Health Organization, 1959b). It was based in part on replies to questionnaires received from 20 countries. The report noted that "it is generally agreed that eradication of smallpox from an endemic area can be accomplished by successfully vaccinating or revaccinating 80 per cent of the population within a period of four to five years". The global programme, as envisaged by WHO, would require national mass vaccination campaigns operated by a smallpox eradication service which would be "integrated with the general public health services" but "directed, or at least co-ordinated, centrally". Freeze-dried vaccine was recommended for use in tropical and remote rural areas and glycerolated vaccine where refrigerated storage and transport were available. The plan proposed that the Organization's Headquarters' budget should make provision for the recruitment of a full-time medical officer, epidemiological consultants (12 man-months per year) and laboratory consultants (6 man-months per year), as well as for the funding of an international conference and 2 training courses on vaccine production, and for the cost of distributing vaccine supplies. WHO regional office budgets would include provision for fellowships and consultants.

The Director-General's report estimated that approximately 977 million people then lived in endemic areas and, if all were to be vaccinated, the cost, calculated at US\$0.10 per person, would amount to about US\$97.7 million (World Health Organization, 1959b). No mention was made in the report of the

Table 9.1. Estimated cost of smallpox eradication as at 1959, and budget for smallpox programmes, 1958-1960 (US\$)<sup>a</sup>

Region	Estimated cost of vaccination	WHO budget		
		1958	1959	1960
Africa	12 810 200	7 300	11 120	0
Americas	10 522 900	114 722 <sup>b</sup>	97 370 <sup>b</sup>	91 718 <sup>b</sup>

Eastern Mediterranean	16 305 900	7 000	28 649	46 236
Western Pacific	3 955 500	0	0	0
Interregional		0	0	38 400
Total	97 742 900	144 532	157 039	190 640
Provided by WHO regular budget		74 197	55 568	111 081

Source: World Health Organization (1959b).

<sup>a</sup> The estimated costs of vaccination were calculated on the assumption that all persons in countries then infected would be vaccinated at a cost of US\$0.10 each. The People's Republic of China, not then a Member State of WHO, was not mentioned in the report, nor were the costs for a programme there included in the estimates.

<sup>b</sup> Includes both WHO and PAHO funds, most of which were allocated to a yaws-smallpox eradication programme in Haiti.

<sup>c</sup> Includes US\$16 000 from UNICEF.

**Resolution WHA12.54, adopted at the Twelfth World Health Assembly in 1959**

"Having considered the report of the Director-General on smallpox eradication [*Official Records of the World Health Organization*, 95, Annex 18],

"Noting:

(1) that although great progress has been made in the eradication of the disease in some areas of the world, important endemic foci of smallpox still remain in other areas, especially in South-East Asia and Africa, from which the disease can be exported to countries already free of it;

(2) that eradication of smallpox from an endemic area can be accomplished by successfully vaccinating or revaccinating 80% of the population within a period of four to five years, as has been demonstrated in several countries;

(3) that sufficient scientific and technical information is available on the production of a suitable smallpox vaccine; and

(4) that although an eradication programme may require, for four or five years, an increase in the national efforts and financial obligations for the intensified campaign against smallpox, the heavy annual burden of continuing expenditure incurred for this purpose may be considerably lightened by increasing the interval between vaccinations once eradication may be considered to have been accomplished,

"1. EMPHASIZES the urgency of achieving world-wide eradication;

"2. RECOMMENDS to the health administrations of those countries where the disease is still present that they organize and conduct, as soon as possible, eradication programmes, making provision for the availability of a potent stable vaccine;

"3. REQUESTS the Director-General:

(1) to urge health administrations of those countries where the disease is still present to develop eradication programmes and to offer them any necessary technical guidance and advice;

(2) to provide for the necessary activities to further smallpox eradication programmes and for the assistance requested by national health administrations for this purpose, in his programme and budget for future years; and

(3) to collect from the countries concerned information on the organization and progress of their respective eradication programmes and to report further to the Thirteenth World Health Assembly."

People's Republic of China, which was not then a Member of WHO. The report pointed out that all countries were already spending considerable sums for the control of smallpox but speculated that the total costs, as estimated for each country, would be "appreciably higher than their present authorized budget provision for this purpose". The WHO budget for smallpox control was noted by the Director-General to have been negligible in previous years except in the Americas, where US\$75 000 had been authorized in 1952 for this purpose, and US\$144 089 in 1954. Although the report pointed out that "large sums are again set aside for the years 1958-1960 to continue the work" (Table 9.1),

it also stated that even larger sums would be required in future years.

The report was discussed both at the Executive Board and subsequently at the Twelfth World Health Assembly (1959), although few substantive comments were made. At the conclusion of the debate, the delegates voted unanimously in favour of the programme. Nothing was said about the wide discrepancy between the identified need and the proposed WHO budget, nor was a request made for additional resources to be provided through voluntary contributions. Indeed, the only doubt about the feasibility of global eradication was expressed by a delegate from South Africa, who indicated that, without

knowing the exact position in all other countries, he could not say whether world-wide smallpox eradication was a practical proposition; nevertheless, he supported the resolution. Other delegates presented encouraging reports on their own successes in undertaking smallpox vaccination campaigns and in producing vaccine. The operative paragraphs of the resolution adopted (see box) were as significant for what was omitted as for what was said. No reference was made in them to the reporting of cases, the containment of outbreaks, or a timetable for the achievement of eradication, whether within a 10-year period, as suggested in the report presented by Professor Zhdanov, or in 5 years, as suggested in the resolution adopted by the Eleventh World Health Assembly.

Although the resources budgeted for the programme were modest indeed, Professor Zhdanov's ambitious proposal had been accepted, at least in principle, and the programme for the global eradication of smallpox formally began.

## HISTORY OF THE CONCEPT OF ERADICATION

### Introduction

The acceptance, as public health policy, of a planned programme designed to eradicate a disease over a large geographical area is a comparatively recent development, and the extension of such a policy to encompass the entire world is an even more recent one (Andrews & Langmuir, 1963). Even in 1958, and indeed for nearly two decades afterwards, the feasibility of global eradication of any disease was by no means universally accepted by the scientific community. However, smallpox was not the first disease to be considered seriously as a target for eradication, nor was the programme the first global campaign to be mounted. Because the personalities, attitudes and practices in previous programmes played an important role in the development and evolution of the smallpox eradication programme, it is important to consider briefly its historical antecedents.

Some would take issue with the assertion that smallpox was not the first disease to be considered for eradication, and in argument cite Jenner (1800) who wrote: "... Cow Pox, an antidote that is capable of extirpating from the earth a disease which is every hour devouring its victims: a disease that has been

considered as the severest scourge of the human race!" Others at this time (Carl, 1802) echoed this belief, but the views were more expressions of hope than expectations for the implementation of a broadly conceived international programme.

Following Jenner's discovery, compulsory vaccination in several European countries resulted in the absence of the disease from a number of them over many years; also, in some small island states and isolated countries, smallpox occurred only sporadically, as a result of importations. However, government authorities, recognizing that smallpox could readily be reintroduced at any time, never spoke in terms of its eradication. The idea was not voiced again until 1949, at which time the Director of the Pan American Sanitary Bureau (the headquarters and secretariat of the Pan American Sanitary (later Health) Organization and WHO Regional Office for the Americas) proposed that such a programme should be undertaken throughout the Western Hemisphere. Meanwhile, efforts to control many other diseases, both animal and human, were being actively pursued.

The possibility of eradicating a disease or its vector emerged as a concept in the late 1800s with the improving scientific understanding of the causation and mechanism of transmission of various diseases and the discovery of methods for preventing them. As applied to a definitive policy, the term eradication appears to have first been used in 1884 in reference to a programme in the USA for the control of an animal disease, bovine contagious pleuropneumonia. Only 4 years later, however, Dr Charles Chapin (quoted in Soper, 1965) was to observe that preventive measures for any disease, if diligently applied, could potentially lead to eradication. He boldly asserted that any disease which could be prevented in part could be prevented in its entirety, and suggested that this might apply specifically to tuberculosis. Gradually, the term eradication came into wider use and, over the years, it was given a variety of definitions. Some authorities asserted that the term should be applied only when a disease pathogen had become extinct throughout the world, while others argued that it could mean simply the reduction in the incidence of a disease to the point where it ceased to be a public health problem (Cockburn, 1963).

In this publication, the term eradication is used in a narrower sense as suggested by its Latin derivation—*eradicare*, literally "to root

out" or "to tear out by the roots". Most eradication programmes, as such, have been concerned with communicable diseases, although diseases induced by toxic substances could certainly be eradicated by eliminating the offending substances. However, to use the term eradication with regard to programmes directed towards preventing traffic accidents or hunger, as some have done, is obviously inappropriate. For communicable disease programmes, Andrews & Langmuir (1963) provide the most widely accepted distinction between control and eradication: "Control is the purposeful reduction of specific disease prevalence to relatively low levels of occurrence, though transmission occurs frequently enough to prevent its permanent disappearance." Eradication, however, as they state, proceeds "to the point of continued absence of transmission within a specified area". While recognizing that the unqualified use of the word eradication signifies the world-wide extermination of a biological species, they accept the use of the word when applied to a specified geographical area—in effect, "area eradication".

The question of how large a specified area must be in order to apply usefully the term eradication has frequently been a contentious issue. Measles illustrates the quandary as to what the lower limits should be. The eradication of measles in a household or district in a city means little, since transmission periodically ceases in such small areas without the application of control measures, and reinfection regularly occurs. But should one speak of eradication of measles from a state or province, for example, or should the notion apply only to a continent or even larger area? Views differ on this question but most epidemiologists now prefer to use the term eradication only when the area covered is sufficiently large and geographically delimited and the characteristics of the disease or vector are such that reinfection or reinfestation is unlikely. Previous successful programmes, which are described below, are by these criteria properly called area eradication programmes.

### **Eradication of Animal Diseases**

For a number of reasons, national programmes to eradicate animal diseases or pests antedate the first human disease eradication programmes and have been more consistently and vigorously pursued over the past century.

To begin with, the measurable economic consequences of animal diseases have usually made it easier to obtain support for animal disease control programmes than for those for human diseases, whose economic consequences are often more difficult to quantify. Moreover, in dealing with animal diseases, useful strategies are available which cannot be employed in controlling human disease, the most important being the ability to apply rigid quarantine measures and to slaughter entire flocks or herds found to be infected. Finally, those concerned with animal husbandry have focused their attention more on the prevention of diseases than on their treatment.

It is not surprising, therefore, that the first planned programme whose stated objective was eradication was one intended to eliminate a disease of cows—bovine contagious pleuropneumonia (Hinman, 1966). This highly fatal disease had been brought from Europe to the USA (New York State) in 1843. Gradually, it spread to the large midwestern cattle-raising areas, and other countries eventually began to embargo imports of livestock from the USA. To deal with the problem, the United States Congress, in 1884, created the Bureau of Animal Industry, whose specific responsibility was to eradicate bovine pleuropneumonia. During a 5-year campaign the disease was eliminated, and the precedent and mechanisms for attacking other animal disease problems were established. Subsequent area-wide eradication programmes, again defined as such, were successfully conducted in the USA against a number of other animal diseases, including glanders (a disease of horses and mules), piroplasmiasis (Texas fever) of cattle, and dourine (a sexually transmitted disease of horses) (Hagan, 1958). Rinderpest and sheep pox were eradicated from most countries in Europe late in the 19th century, and early in the present century eradication was accepted as the standard procedure for dealing with importations of serious exotic diseases of livestock into the industrialized countries of Europe, North America and Oceania.

The strategy differed from disease to disease, the approaches adopted depending on the mode of spread of the disease and the most effective point in the cycle of transmission at which to intervene in order to stop dissemination, whether by the isolation and slaughter of infected herds or the killing of vectors. Specific characteristics of the diseases in

question were vital to the success of these efforts, among the most important being that the diseases had been introduced comparatively recently into the target areas from other countries and that they tended to be geographically circumscribed. Moreover, it was usually possible to diagnose them easily, subclinical infections and carriers were rare, and none had become enzootic in wild animals. Success in solving the diverse problems involved suggested that there might be a number of microorganisms which clung so tenuously to an ecological niche that simple measures could be found to upset the balance of nature. Intensive, albeit costly, short-term programmes in these instances could be more productive and ultimately less expensive than long-term control efforts and the acceptance of continuing damage to livestock.

Thus, planned programmes for disease eradication on a national scale were a familiar concept to workers in veterinary medicine, but the achievements of such programmes were largely unknown to those concerned with human disease. For human diseases such as smallpox, cholera, plague and yellow fever, quarantine regulations were adopted to prevent their introduction into a country, and, in the case of smallpox, intensive vaccination campaigns were conducted when the disease was imported into smallpox-free areas. Until the present century, however, the term eradication, in the sense of a planned programme whose stated aim was the elimination of a human disease throughout a defined geographical area, was not used.

#### **The First Eradication Programmes for Human Diseases—Hookworm and Yellow Fever**

Hookworm was the first disease to be considered seriously as a candidate for global eradication, and the first for which a programme was actually mounted. That programme, begun in 1909, was soon followed by a global programme for the eradication of yellow fever. Since the operational methods and styles of leadership adopted in subsequent eradication programmes had their roots in these two campaigns, their history is of interest.

From what is now known of the biology of the two diseases, neither was a reasonable candidate for eradication, but, when the programmes began, inadequate scientific

knowledge, coupled with a visionary outlook and excessive optimism, made them appear suitable. The extensive campaigns which ensued left an important legacy in the development of public health services and education in many countries. But, as the programmes progressed and more was learned about these and other diseases, it became increasingly apparent that the causative organisms were remarkably well adapted to their ecological niches and had more intricate and complex relationships with the human and natural environments than had been appreciated. Gradually, it became apparent that disease eradication was a formidable, perhaps even an unattainable, goal (Smith, 1934; Burnet, 1940; Dubos, 1959, 1965).

#### *Hookworm eradication*

Early this century, a United States public health official, Dr Charles Wardell Stiles, had the vision of totally interrupting the spread of hookworm in the southern states of his country by a systematic campaign in which infected persons would be identified by stool examination and their infections eliminated by drug therapy. The construction of sanitary privies during this period would prevent faecal contamination of the soil and thus break the transmission cycle, in which hookworm larvae enter the human body through the skin of the feet, migrate to the intestinal mucosa where they feed on blood in the capillaries, and shed eggs that are passed in the faeces to the soil and there develop into larvae. Advisers to Mr John D. Rockefeller, then increasing his support to philanthropic projects, studied the proposition and pronounced it sound. The Rockefeller Sanitary Commission for the Eradication of Hookworm in the United States was established in 1909, and a sum of US\$1 million was pledged to be spent over 5 years. Dr Wickliffe Rose, a professor of philosophy, was appointed director of the programme.

Over the first 5 years of the hookworm eradication programme in the USA, extensive operations were carried out in 11 states. By 1914, the Commission reported having screened more than 2 million persons, of whom 500 000 were treated in mobile dispensaries; more than 250 000 rural homes were inspected by sanitary personnel. This undertaking, involving thousands of workers, was the largest and most complex community-

wide health programme ever to be carried out in the USA up to that time.

With the establishment in 1913 of the Rockefeller Foundation, Dr Rose was made Director of its International Health Commission, into which the Sanitary Commission was incorporated. The Foundation made a policy decision to "confine itself to projects of an important character, too large to be undertaken, or otherwise unlikely to be undertaken, by other agencies" and to "go to the root of individual or social ill-being and misery" (Fosdick, 1952). Hookworm eradication clearly satisfied these criteria. Thus, as its first initiative, the Foundation's trustees decided "to extend to other countries and people the work of eradicating hookworm disease as opportunity offers, and so far as practicable to follow up the treatment and cure of the disease with the establishment of public sanitation and the spread of scientific medicine". In the following years, cooperative programmes were extended to 52 countries on 6 continents and to 29 island groups.

Not for a number of years were careful field studies conducted to determine whether, given effective execution of the prescribed strategy and tactics, the parasite had actually been eradicated. When such studies were finally conducted, they showed that, even with an effective programme, infection rates did not significantly diminish, although those infected had fewer worms and therefore less illness due to the disease (Smillie, 1922). It was apparent that the biology of hookworm was far more complex than had been appreciated, and that the methods of attacking it were inadequate. Dr William Cort, then the leading authority on hookworm disease, pleaded for more research in both areas but, in doing so, studiously avoided using the word "eradication" (Cort, 1921); the Foundation, at least so far as hookworm was concerned, eventually followed suit. The control programme was remarkably successful in establishing a network of 4-person county health departments (health officer, sanitary engineer, public health nurse and secretary) in the southern USA, and many other countries created similar structures, but hookworm has remained a problem in most developing countries.

#### *Yellow fever eradication*

Success in the control of yellow fever in Cuba and Panama laid the groundwork for yet another, apparently more plausible, pro-

gramme for disease eradication for which the Rockefeller Foundation was also to provide leadership and substantial support. Recurrent severe epidemics of yellow fever had plagued cities in the USA since the 17th century, but the disease had never become endemic. By the end of the 19th century, it was believed that most of these epidemics were the consequence of importations of the disease from Cuba (Strode, 1951). Thus, when Cuba was occupied by United States forces in 1898, during the Spanish-American War, yellow fever control was of special interest to the authorities.

In 1900, a government Yellow Fever Commission, directed by Major Walter Reed, was charged with the responsibility for ascertaining the cause and mode of spread of the disease and for finding methods for its control. A series of brilliant studies rapidly provided the critical insights into the epidemiological behaviour of the disease that permitted an effective control programme to be implemented. Building on the belief of the Cuban scientist, Dr Carlos Finlay, that a mosquito vector was involved, the Commission demonstrated conclusively that the vector was the mosquito *Stegomyia fasciata* (*Aedes aegypti*), which bred almost exclusively in and around houses. Moreover, drawing on observations by Dr Henry Carter, the Commission showed that there was an interval of 9-16 days between the time at which a mosquito took a blood-meal and the time at which it could transmit infection, and that person-to-person spread via excreta or fomites never occurred (Reed et al., 1900). If mosquito control measures were to be introduced and patients isolated in screened quarters, the prospects for yellow fever control looked hopeful.

The Chief Sanitary Officer for Cuba, Dr William Gorgas, then a major in the United States Army Medical Corps, assumed responsibility for the programme. Patients were isolated in screened quarters, and breeding sites for the mosquitoes were eliminated by the removal of discarded cans and bottles, in which they bred; in addition, cisterns were covered with netting and kerosene was applied to water surfaces which could not be otherwise treated (Gorgas, 1911b). The programme was a quasi-military operation, which began on 4 February 1901 and in which teams of 3 inspectors were assigned responsibility for groups of 1000 houses, to be inspected at the rate of 30 houses per day. On

28 September 1901, the last case of yellow fever occurred in the city of Havana proper, only 8 months after the programme had begun—indeed, some 2 weeks before Reed & Carroll (1902) discovered that the disease was caused by a filterable virus. Shortly thereafter, the disease was discovered in a suburb of Havana, but similar operations there promptly terminated transmission and yellow fever vanished from Cuba. Dr Gorgas, in his report of 12 July 1902 to Brigadier General Leonard Wood (Gorgas, 1911a), stated: "I look forward in the future to a time when yellow fever will have entirely disappeared as a disease to which man is subject, for I believe that when the yellow fever parasite has become extinct it can no more return than the dodo or any other species of animal that has disappeared from the earth."

The efficacy of the measures taken was soon confirmed in Panama. In June 1904, Dr Gorgas was named Chief Sanitary Officer for the Isthmus of Panama, where the Panama Canal was then under construction. After an epic 16-month effort, Panama also became free of yellow fever (McCullough, 1977). Success was achieved even though the campaigns were restricted to urban areas, and the vector was substantially reduced in numbers but not eliminated. In 1908, Dr Oswaldo Cruz added independent confirmation of the efficacy of Dr Gorgas's methods by eliminating yellow fever from Rio de Janeiro. On the basis of these experiences, Dr Gorgas concluded that the transmission of yellow fever could be sustained only in the more densely populated urban areas and that eradication could be achieved by short-term campaigns against *A. aegypti* in a few key endemic urban centres (Gorgas, 1908).

Some 6 years later, in 1914, the desirability of testing this hypothesis on a wider scale was suggested to Dr Rose during a visit to Asia. Throughout Asia, he found health officials to be profoundly concerned that yellow fever might be imported as a consequence of the opening of the Panama Canal in that year and the resulting increase in maritime traffic. Although yellow fever did not then occur in Asia (nor is it known to have occurred since that time), the potential mosquito vectors were widely prevalent. If the disease were introduced, massive epidemics could be expected. Dr Rose consulted Dr Gorgas, then Surgeon-General of the United States Army, who expressed the opinion that yellow fever could be "eradicated from the face of the earth

within a reasonable time and at a reasonable cost" (Fosdick, 1952). On 26 May 1915, definitive action was taken by the International Health Commission to set such a programme in motion, by its adoption of the following resolution:

"Whereas, yellow fever has been endemic in tropical and subtropical America for centuries, constituting a serious menace in the infected areas and a perennial source from which epidemics have spread to more remote regions both in America and Europe, involving great loss of life and interrupting industry and trade over vast areas, and

"Whereas it has been shown by the work done in Havana and Panama under the direction of Dr William C. Gorgas and in Rio de Janeiro under the direction of Dr Oswaldo Cruz that the infection can be eradicated even in communities where it is endemic, and

"Whereas, the opening of the Panama Canal and the changing of trade relations resulting therefrom have given rise to widespread apprehension that yellow fever may be introduced into the Orient; and that once endemic in these densely populated regions it would become a permanent menace to the rest of the world; therefore

"Be it resolved, that the International Health Commission is prepared to give aid in the eradication of this disease in those areas where the

JOHNS HOPKINS UNIVERSITY, 1916

**Plate 9.2.** William Crawford Gorgas (1854-1920), after successfully freeing Cuba and Panama of yellow fever, encouraged the Rockefeller Foundation to support a global effort to eradicate the disease. Launched in 1918, with Gorgas as director, this work was the first serious attempt to eradicate a human disease. Its principal technology, vector control, became the basis of subsequent efforts to eradicate the mosquito vectors of malaria and other diseases.

infection is endemic and where conditions would seem to invite cooperation for its control." (Strode, 1951.)

It was anticipated that eradication in the Americas would require perhaps 5 years; further study would be needed to determine a timetable for Africa, the only other endemic area. Soon afterwards, a resolution calling for the eradication of yellow fever from the Americas was approved by the II Pan American Scientific Congress (1915-1916) (Duffy, 1977). Between 1916 and 1949, the Rockefeller Foundation was to spend US\$13.8 million on yellow fever control (Strode, 1951).

With the new yellow fever eradication programme and a continuing campaign against hookworm, a critical need arose for skilled physicians trained in organization and management and having a scientific understanding of these diseases. Partly to meet this need, Dr Rose proposed in 1916 that schools of public health should be founded with support from the Rockefeller Foundation. The first of these was established at The Johns Hopkins University. Over the succeeding decade, 23 other schools based on this model were established and supported in 20 different countries in North and South America, Europe and Asia.

The start of the yellow fever eradication campaign was delayed by the First World War, but in 1918 programmes supported by the Rockefeller Foundation were launched in Guayaquil, Ecuador, and in towns on the Pacific coast of South America at risk of infection from Guayaquil. They were soon extended to other known or suspected foci in the Central American countries, Mexico and Peru. The campaign was predicated on the belief that there was no animal reservoir and that yellow fever was unable to persist as an endemic disease in urban populations of less than 50 000. Campaigns to interrupt transmission were thus conducted only in the cities and larger towns but were extended to smaller towns to control outbreaks when they occurred. Transmission appeared to cease when breeding sites of *A. aegypti* were found in only 5% or fewer of the houses, and thus control, not eradication, of the vector constituted the basic strategy. At first it was dramatically successful. Transmission ceased in Guayaquil after only 6 months, in Peru in 1921 and in Central America in 1924.

Brazil organized its own programme in 1919 but halted it in 1922 when the "disease

had disappeared from the statistics" (Soper, 1965). Yellow fever reappeared in 1923, however, and the Rockefeller Foundation was requested to provide support. Again, rapid progress was made, and from April 1927 to March 1928 no cases were reported from anywhere in the Americas. Meanwhile, in preparation for programmes in Africa, the Rockefeller Foundation established laboratories there to undertake special studies of the disease.

In March 1928, however, cases of yellow fever were again detected in north-east Brazil and, in May, cases appeared in the capital, Rio de Janeiro—the first cases there since Dr Cruz's campaign 20 years before. From Rio, cases spread rapidly and widely throughout the country, the first such spread of yellow fever from a key urban centre since the programme had begun. At the same time, outbreaks whose sources could not be identified occurred also in Colombia and Venezuela. Many people began to express doubts about the feasibility of yellow fever eradication, and the Rockefeller Foundation, simultaneously faced with a failing anti-hookworm campaign, began to be criticized for its support of disease eradication (Soper, 1965).

The crisis of the Rio de Janeiro epidemic precipitated a series of changes which, in turn, altered the administrative structure of the programme and eventually led to a redirection of its goals. At the same time, it established precedents for centralized, independent programme operations which were to characterize subsequent malaria eradication programmes. Field activities, previously directed by a combination of national and state authorities and Foundation staff, were integrated over a 3-year period into a single National Yellow Fever Service under the direction of Dr F. L. Soper, a Foundation staff member who had worked in the anti-hookworm campaign in Brazil since 1920. No national disease control programme of such magnitude had been undertaken before this time. It was supported in part by the Brazilian government and in part by the Foundation.

The 1928-1929 outbreaks, some of which occurred outside urban areas, dramatized the need for disease surveillance. Information as to where yellow fever was occurring was vital but until 1930, there was no organized system for detecting and reporting cases. Because programme staff had assumed that endemic disease could persist only in urban areas with populations of 50 000 or more, and because

the disease was severe and often fatal, they believed that the presence of yellow fever would inevitably become known without much delay. In fact, few hospitals or health units outside urban areas regularly reported suspected cases, and from most areas there were no reports at all. Not until 1930 was it appreciated that the absence of reports did not necessarily mean the absence of cases. To obtain accurate reports, however, was difficult because, clinically, yellow fever resembled other illnesses with fever and jaundice. Neither virology nor immunology was then sufficiently advanced for satisfactory diagnostic methods to have been developed, but, fortunately, the liver pathology of patients with yellow fever was characteristic of the disease. Thus, pathological diagnosis was employed to determine the etiology in fatal cases. To obtain the necessary specimens, the Brazilian government ordered that a specimen of liver should be obtained from all patients who had died within 11 days of the onset of a febrile illness (Soper et al., 1934). A viscerotome was devised (Rickard, 1931) that was simple enough to be used by a layman after brief training. A field organization of viscerotomists was set up, a small payment being made for each specimen provided. It soon became apparent that there was widespread endemic disease in rural areas of the north-east (Soper et al., 1933), and in 1932 the first definitive evidence was obtained that wild animals constituted a jungle reservoir of the disease (Soper, 1936), a fact soon confirmed in other countries.

### *Aedes aegypti* Eradication

With the discovery of the existence of a virus reservoir in wild animals, the eradication of yellow fever was no longer realistic. However, in the course of reorganizing the yellow fever programme, Dr Soper had established a rigidly disciplined and meticulously organized vector control programme in coastal cities throughout north-east Brazil. It soon became apparent that in urban areas, the peri-domestic *A. aegypti* mosquito could be entirely eliminated through the removal or destruction of breeding sites around human habitations. Reintroduction occurred, however, unless suburban areas were similarly controlled, and this implied that eventually programmes would be required in the interior of the country as well. A programme for the

eradication of a mosquito species was an entirely different proposition from one designed only to reduce it to low levels. It required a far more intensive and disciplined effort over a far wider area and for a much longer time than that needed for the Gorgas-type yellow fever eradication programme in Havana. However, in view of the already considerable investments of the Brazilian government and of the Rockefeller Foundation and the existence of a highly disciplined organization in the field, Dr Soper in 1934 proposed a new objective—the eradication of *A. aegypti*, the urban vector of the disease. This was the strategy that he subsequently pursued, although it did not become the declared policy of the Brazilian National Yellow Fever Service until 1942.

With the eradication of yellow fever no longer feasible and that of *A. aegypti* a more costly and less certain proposition, the Rockefeller Foundation decided to withdraw its support but, because of Dr Soper's position, this was diplomatically difficult. Dr William Sawyer, of the Foundation, wrote to him on 24 September 1935 stating: "The yellow fever service has grown to such a size that you have practically become a Government official in charge of a large division of the Health Department ... it is hardly consistent with our general policies" (Duffy, 1977). The decision to withdraw support was postponed on several occasions at the request of the Brazilian government, but finally, at the end of 1939, support ceased and responsibility for the programme in Brazil was transferred from the Foundation to the government. Dr Soper, however, remained on the staff of the Foundation.

### Eradication of Another Mosquito Vector—*Anopheles gambiae*

Because of the failure to eradicate yellow fever, the concept of eradication might well have been more thoroughly discredited had it not been for the unexpected discovery and the subsequent elimination of a focus of the mosquito *Anopheles gambiae*, near Natal in north-east Brazil (Duffy, 1977). This African mosquito, an exceptionally efficient vector of malaria, was apparently imported into Brazil in about 1930, soon after the establishment of a rapid mail service between Dakar (Senegal) and Natal (Soper & Wilson, 1943). Epidemic malaria occurred that year within an area of a

few square kilometres in which the mosquito was first found. Although the vector was quickly eliminated from Natal, it spread inland, and in 1938 severe epidemics began to occur over large areas of 2 states. In all, 31 000 square kilometres were found to be affected (Fosdick, 1952). Dr Soper proposed that an *A. gambiae* eradication programme should be started immediately. He rightly portrayed—in the most dire terms—the implications of a continent-wide spread of the mosquito, but support was not immediately forthcoming from either the Rockefeller Foundation or the Brazilian government. To some, it was seen as little more than an excuse to prolong the life and extend the scope of the vector control services. However, in January 1939, with reluctant financial support from the Foundation as well as substantial government funds, an anti-malaria service was established by presidential decree, its direction being entrusted to the Foundation and to Dr Soper.

The problem was a major one, more than 100 000 cases of malaria being detected in May 1939 alone, but the strategy required was entirely different from that used to eliminate *Aedes aegypti*. *Anopheles gambiae* bred widely in shallow pools of residual rain-water which were exposed to the sun and without vegetation. It did not usually lay eggs in deep or running water or water which was salty or shaded. During the 4-month rainy season in the area concerned, breeding took place in any small depression in the ground, such as wheel tracks and hoofprints, which could retain water for 8–9 days. With the advent of the dry season, however, the tropical sun and low humidity restricted breeding essentially to isolated pools in the beds of large rivers.

The approach which was adopted required a staff of about 4000. The boundaries of the infested area were determined and posts established at which all vehicles and boats leaving the area were fumigated. In the infested areas, vector control staff carried out regular inspections, applying Paris green to all possible breeding sites and spraying houses with pyrethrum (Duffy, 1977). They were able to do little more than control breeding during the rainy season, but when the dry season came and breeding sites were few, large areas could rapidly be cleared of the vector. A rigorously disciplined and closely supervised vector control staff, organized with the meticulous attention to detail which had characterized the *Aedes aegypti* programme, succeeded in these efforts, the last focus of

*Anopheles gambiae* being discovered in November 1940, less than 2 years after the campaign had begun.

Although *A. gambiae* was a recently introduced vector and less well established in Brazil than in its native African habitat, its eradication from Brazil was nevertheless a dramatic achievement which, at the outset of the programme, had been considered by most to be hopelessly unrealistic. From the experience of this campaign, as well as those against *A. aegypti* and the Mediterranean fruit fly in Florida (USA), Dr Soper concluded that "selective species eradication", not only of *A. gambiae* but of other vectors as well, was in many instances a sound and ultimately less expensive approach than the control of the vector and of the disease (Soper & Wilson, 1943). The belief was reinforced when, in July 1944, he assumed direction of an *A. gambiae* eradication programme in Egypt, into which the vector had apparently been introduced in about 1942, causing major epidemics of ma-

WHO/T. FARKAS, c. 1966

**Plate 9.3.** Fred Lowe Soper (1893–1977) was the most ardent proponent of the policy of disease eradication. While on the staff of the Rockefeller Foundation, he directed the yellow fever eradication programme in Brazil in the 1930s, a programme he transformed into one designed to eradicate the principal mosquito vector (*Aedes aegypti*). Subsequently, he directed programmes to eradicate infestations of *Anopheles gambiae* in Brazil and Egypt. As the Director of the Pan American Sanitary Bureau, 1947–1959, he was instrumental in persuading the Pan American Sanitary Organization to embark on regional programmes for the eradication of *A. aegypti*, smallpox, yaws and malaria.

laria. An estimated 120 000 deaths had already occurred when the Egyptian government requested the help of the Rockefeller Foundation and Dr Soper (Duffy, 1977). Employing the same manual and methods as had been used in Brazil, an effective campaign quickly took shape and, in February 1945, the last focus was eliminated.

As Dr Soper saw it, success lay in "vigorous and effective action rather than refined measurement of the problem" (Duffy, 1977). He had no malariologists on his staff and saw no need for them. He quoted Dr Ronald Ross (Ross, 1911) on the need for "learning by doing":

"Amateurs are fond of advising that all practical measures should be postponed pending carrying out detailed researches... In my opinion this is a fundamental mistake... In practical life we observe that the best practical discoveries are obtained during the execution of practical work and that long academical discussions are apt to lead to nothing but academical profit." (Soper & Wilson, 1943.)

Dr Soper's advocacy of, and belief in, the principle of eradication was a major factor in later decisions to undertake other eradication programmes. The major constraints, he believed, lay primarily in the lack of vision of health administrators rather than in the lack of appropriate technology. With a meticulously executed field programme directed by dedicated and imaginative staff, the inconceivable became possible.

As early as 1934, Dr Soper had been convinced of the feasibility of eradicating *A. aegypti* from the Western Hemisphere. His opportunity to pursue the matter came in 1947 when he was elected Director of the Pan American Sanitary Bureau (PASB). He was a forceful and imaginative administrator, who extended and reoriented PASB's activities, converting it from a body which dealt principally with matters of international quarantine and was staffed entirely by officers seconded from the United States Public Health Service, into the secretariat of a fully fledged international organization, the Pan American Sanitary (later Health) Organization (PASO, later PAHO). One of the first acts of the Directing Council of PASO, in September 1947, was to adopt a resolution:

"1. To entrust to the Pan American Sanitary Bureau the solution of the continental problem of urban yellow fever, based fundamentally on the eradication of *Aedes aegypti*...

"2. To develop the program under the auspices of the Pan American Sanitary Bureau, which... shall take the necessary measures to solve such problems as may emerge... whether they be sanitary, economic or legal." (Pan American Health Organization, 1971a).

As Dr Soper noted, "For the first time the governments of an entire region committed themselves to the continental solution of a common health problem" (Soper, 1965). Ironically, the goal was never achieved. At one time or another *A. aegypti* eradication was certified in all the countries of the Americas except Colombia, the USA, Venezuela and some of the Caribbean islands. However, reinfestations repeatedly occurred and a US\$54 million programme in the USA, which was not begun until 1964, was terminated in 1968, its failure resulting to a large extent from the fact that there were substantially more breeding sites than had been anticipated and that vector control staff could not legally be given the unrestricted right of entry to all premises to look for them (Fontaine et al., 1965).

### Programmes for the Eradication of Malaria, Yaws and Other Human Diseases

Dr Soper's advocacy served to encourage acceptance of the principle of eradication as the defined objective of disease control programmes. Resolutions were adopted uncritically supporting the eradication of other diseases, only limited consideration being given to the technical feasibility, the available resources or the strategy to be used. The XIII Pan American Sanitary Conference (1950) committed PASB to regional programmes for the eradication of yaws, malaria and smallpox. Later, the World Health Assembly committed WHO to global eradication programmes for malaria (1955) and smallpox (1959). Events leading to the decision to undertake the eradication of smallpox are described in a subsequent section, but a brief description of the other initiatives and their outcomes is pertinent.

#### The malaria programme

Of all the eradication programmes, that for malaria represented by far the largest commitment, in terms both of the number of countries involved and of the resources de-

ployed. It was, moreover, the only global disease eradication programme other than that for smallpox to be approved by the World Health Assembly. Because malaria eradication activities antedated those of the smallpox eradication programme and continued through much of its course, they are of special interest. The successes and failures of its policies provided guidance in formulating smallpox eradication strategy, and its continuing operations competed both for resources and for the attention of national and international authorities until the mid-1970s.

Malaria was and is one of the most serious of the health problems of tropical and sub-tropical countries throughout the world. Until the Second World War, the principal control methods available were costly ones—drug therapy for the disease and mosquito control through environmental management and the application of chemicals to destroy larvae and adult mosquitos. Where these measures were diligently applied, especially in areas in which mosquitos did not breed throughout the year, reasonable control could be achieved; such cases as did occur could be treated, usually successfully, with drugs. In few of the non-industrialized countries, however, was it possible to achieve such control measures outside urban centres.

However difficult the control of malaria, the idea that eradication was possible was raised as early as 1916 (Hoffman, 1916) and actually adopted, in part, in a resolution of the II Pan American Scientific Congress in January of that year, which urged "... that all American countries inaugurate a well-considered plan of malaria eradication and control" (Jeffery, 1976). Little was achieved, but in the early 1940s the discovery of the insecticide DDT radically changed the situation. DDT, it was found, had a remarkable property in that it retained its toxicity for mosquitos over many months when applied to surfaces (Soper et al., 1947). Most malaria-bearing anophelines, after taking a blood-meal, rested on a nearby surface. If this was a wall coated with DDT, they died before they could transmit the disease.

As increasing quantities of inexpensive DDT became available, it was used in many malaria control programmes in different parts of the world. The effect on malaria morbidity and mortality was dramatic. In Venezuela, for example, in states with an accurate death registration system, mortality rates plummeted from a median of 173 per 100 000 popula-

tion in 1941–1945 to 2 per 100 000 in 1949 (Gabaldón, 1951). Similar results were observed in countries as distant and disparate in character as Ceylon (Sri Lanka) and China (Province of Taiwan). The complete disappearance of malaria from infected areas in Greece and Italy, as well as from the whole of Sardinia, was even more dramatic (Logan, 1953). Of particular interest was the discovery in Greece that even when DDT spraying was temporarily stopped owing to a shortage of the insecticide, the disease did not return (Pampana, 1963). A DDT-based malaria eradication programme throughout infected areas of the USA (Andrews, 1951) also appeared to have stopped transmission towards the end of the 1940s, although surveillance data collected at a later stage revealed that the campaign had actually begun some time after transmission had effectively been stopped by traditional measures (Langmuir, 1963).

These successes, real or imagined, spurred the imagination of the eradicationists. Thus, in 1948, Dr E. J. Pampana proposed that global malaria eradication should be undertaken (Pampana, 1948). This proposal was translated into policy 2 years later, in 1950, when the XIII Pan American Sanitary Conference, encouraged by Dr Soper, recommended that PASB should "collaborate with

**Plate 9.4.** Emilio J. Pampana (1895–1973), a distinguished Italian malariologist, in 1948 proposed the global eradication of malaria, a commitment adopted by the World Health Assembly in 1955. He was on the WHO staff from 1947 to 1958, first as chief of the malaria section, later as the first Director of the Division of Malaria Eradication.

the malarious nations of the Americas in national malaria eradication programmes" (Pan American Health Organization, 1971a). Little note was taken of the fact that malaria transmission had so far been interrupted only in the more developed areas of the world or where the mosquito vector was able to breed for only part of the year.

The financial and personnel resources of PASB were limited, and, as Dr Soper was to observe: "The action of the conference on malaria eradication proved to be ahead of its time; the PASB itself was not sufficiently developed to give adequate leadership" (Soper, 1965). During the succeeding 4 years, the successful use of DDT was reported from other countries but further progress in malaria eradication in the Americas was limited. Although United States bilateral assistance for malaria control in the Americas amounted to US\$60 million between 1942 and 1957 (International Cooperation Administration, Expert Panel on Malaria, 1961), this was far too little to tackle the problem seriously.

Greater international support was required. The key to obtaining that support was provided by the first scattered reports, in 1951, of mosquito resistance to DDT—the insecticide on which the whole programme of malaria control depended (Pampana, 1963)—thus raising the spectre of widespread vector resistance that would render DDT useless as a means of control. It was argued that, in view of this situation, the only workable strategy was to carry out an intensive global programme to eradicate malaria before the problem of resistance became widespread. When confronted with this scenario, the XIV Pan American Sanitary Conference, in October 1954, declared regional malaria eradication to be an emergency need and authorized a special fund of US\$100 000 for administrative expenses (Pan American Health Organization, 1971a). Immediately thereafter, UNICEF also agreed to provide support (Soper, 1960).

By no means were all scientists convinced that eradication was a feasible objective, given the tools available (Farid, 1980; Downs, 1981). For Dr Soper, however, the answer, as with his *Aedes aegypti* and *Anopheles gambiae* campaigns, lay in an aggressive approach, in meticulous organization, and in tackling the problems as they emerged. As he was to point out later, the eradication programme for *A. aegypti* had required no new technical or administrative methods—merely the careful

supervision and checking of work and the standardization of operating procedures. He believed that there was an "essential identity of the malaria program with that of yellow fever" (Soper, 1960). To subscribe to the objective of malaria eradication required an act of faith. To those who doubted, Dr Soper quoted the pessimistic 1945 Presidential Address of the sceptical Dr Henry Johnson, President of the National Malaria Society in the USA: "I feel this [malaria eradication in the USA] is an untenable concept as we do not yet know in sufficient detail just where and under what conditions the disease occurs" (Johnson, 1946). It became apparent only a few years later that malaria eradication in the USA was imminent, if not already achieved, even as Dr Johnson spoke.

In May 1955, less than a year after the Pan American Sanitary Conference decided on an emergency programme for the eradication of malaria from the Americas, the Eighth World Health Assembly endorsed this as a world-wide policy, and WHO was committed to its first global eradication programme. In the words of resolution WHA8.30, the Health Assembly:

"Considering that the ultimate goal of malaria-control programmes should be the eradication of the disease,

1.1. REQUESTS governments to intensify plans of nation-wide malaria control so that malaria eradication may be achieved and the regular insecticide-spraying campaigns safely terminated before the potential danger of a development of resistance to insecticides in anopheline vector species materializes." (World Health Organization, 1973a.)

A Malaria Eradication Special Account for voluntary contributions was created and programmes began throughout much of the world, although not in sub-Saharan Africa.

The WHO Expert Committee on Malaria, which met a year later, was extremely cautious, however, when it discussed the feasibility of malaria eradication. In its report, it noted only that eradication "has been accomplished and has shown that it can withstand the test of time in a number of areas in the Mediterranean countries and the Americas" and that "malaria eradication might have still remained an exceptional aim if events had not made it a preferable one to mere control" (WHO Expert Committee on Malaria, 1957). Nothing was said, or could be said, about the prospects for eradication in sub-Saharan Africa in particular. No successful national programmes had been carried out there, most

### Unacceptable Doubts about Malaria Eradication—Reflections of Dr Wilbur Downs

"In the early 1950s, when malaria eradication became the cause, Dr. Soper came to Mexico to persuade Mexico to get aboard the band wagon. Since I was in Mexico and had been there for 6 years, I was summoned to be with Soper in the office of the Ministry of Health, where multimillion dollar issues were being discussed. My own program budget at the time was less than \$50,000 per annum. As I sat in the Minister's office, I heard some amazing things being said, things quite opposite to my own experience, and spoke up saying that there was evidence to indicate very serious problems in the way of eradication in Mexico. Some problems related to the unreconstructed habits of the principal vectors, *Anopheles pseudopunctipennis* and *Anopheles albimanus*. Some problems related to the absorption and accelerated decomposition of DDT by the clays found in the mud of adobe walls. Soper strode over to me, put both hands around my neck and shook me vigorously, saying at the same time that it was this kind of talk which was impeding the malaria eradication effort around the world. Not long after that episode, I was advised by my organizational superiors that my malaria study project in Mexico was superfluous, and would be terminated." (Downs, 1981.)

of the countries concerned were at an early stage of development and there was year-round breeding of the vectors in many areas. Given these and other problems, there was good reason to believe that eradication could not be achieved (Macdonald, 1957). Little mention was made by WHO thereafter of the fact that "Africa south of the Sahara was at present excluded from the eradication programme, for physical, economic and developmental reasons complicated by high endemicity and prolonged transmission factors" (World Health Organization, 1957).

The visionary goal of the global eradication of a disease as serious as malaria was enthusiastically welcomed by politicians and agencies around the world, as well as by those concerned with public health. The programme was foreseen to be a costly one but it was supported by multilateral and bilateral agencies as no previous international health undertaking had ever been. At the same time, participation by countries in a fully fledged eradication effort was encouraged by the policy of providing funds only to countries which agreed to accept the objective and strategies of eradication. By 1958, 63 countries had either started malaria eradication programmes or had converted their control programmes to eradication campaigns; 700 million people, 65% of the population in malarious areas, lived in these countries (Yekutieli, 1981).

Increased expenditures from the WHO regular budget were substantially augmented

by voluntary contributions to the WHO Malaria Eradication Special Account, and supported by other funds administered by WHO, including those provided by UNICEF and the United Nations Expanded Programme of Technical Assistance (later named the United Nations Development Programme) (Table 9.2). The malaria eradication programme quickly became WHO's most important activity and in 1962, when contributions to the Special Account diminished, funds from WHO's regular budget, although originally intended for other purposes, were transferred to the Special Account. Expenditures from funds administered by WHO increased from US\$2.4 million in 1955 to US\$13.7 million in 1958; the number of staff posts likewise increased, from 84 in 1955 to 259 in 1958 and to 577 in 1960. From 1955 to 1958, the malaria eradication programme accounted for 3.6% of WHO's regular budget and 34.8% of all funds and its disposal (Table 9.3). Between 1959 and 1966, obligations for malaria eradication increased substantially, accounting for 10.8% of WHO's regular budget and 27.2% of all funds placed at the Organization's disposal. In comparison, smallpox control received little support and, after the global eradication programme began in 1959, expenditure remained below 1.0% until 1967. Bilateral contributions to national programmes were also greatly augmented and national government budgets were vastly increased. An estimated US\$1400 million were expended from all sources for malaria

Table 9.2. Number of WHO staff posts and estimated expenditure for malaria eradication from the WHO regular budget and from funds provided to WHO through the Malaria Eradication Special Account and by other international agencies, 1955-1970<sup>a</sup>

<sup>a</sup> Estimates derived from WHO financial reports, WHO proposed programme and budget volumes and reports to the Directing Council of PAHO.

<sup>b</sup> United Nations Expanded Programme of Technical Assistance, UNICEF, PAHO regular budget and PAHO special malaria fund.

<sup>c</sup> In 1962, 1963 and 1964, WHO regular budget funds were transferred to the Malaria Eradication Special Account in amounts, respectively, of US\$2 million, US\$4 million and US\$5 363 000 (World Health Organization, 1963a, 1964a, 1965a). These expenditures are shown in the table as regular budget expenditures, which accounts for an apparently negative expenditure figure from the WHO Special Account in 1964.

eradication between 1957 and 1967, and US\$1000-1200 million over the succeeding 8 years (United States Agency for International Development, 1983).

In its organization and relationship to other public health activities the malaria eradication programme resembled the *Aedes aegypti* eradication programme in Brazil, as it called for a distinct and separate malaria eradication service which would have no other duties. In most countries, the malaria programmes were by design entirely independent of the health authorities, reporting only to a national council and thence to the head of state. The WHO Expert Committee on Malaria (1957) saw the malaria eradication staff as serving eventually as a nucleus for other public health programmes, but believed that it should not merge with other activities until success had been achieved. There were some grounds for this view, because the nature of the field work—namely, house-to-house visits and insecticide spraying—differed from that normally carried out by health staff. Moreover, many more field staff were required for malaria eradication than for any other health programme involving field activity. Indeed, in some countries, malaria eradication staff eventually outnumbered the

personnel of all other government health programmes combined.

In addition, malaria eradication staff were generally of higher calibre than other comparably trained health workers and their pay scales were almost always higher. It was inevitable, therefore, that the all but autonomous, independent malaria eradication services, with their more highly paid and better supported staff, would be resented by those in the health services—and they were. As a consequence of this programme, there gradually arose a belief, held with almost ideological fervour, that a "vertical" programme—i.e., virtually any organized programme in which staff were responsible for attaining objectives specific to a particular disease—was a heresy. Later efforts to develop smallpox eradication programmes, even though as an integral part of the health service structure, were often met with hostility; the assistance or even passive cooperation of the malaria eradication services was obtained only with the greatest difficulty, or not at all.

The systematic application of DDT to the walls of all houses and buildings was the principal element in the strategy, although this was supplemented in the later phases of each campaign with the treatment of cases

Table 9.3. Expenditure<sup>a</sup> of funds placed at the disposal of WHO from all sources, for all purposes, for malaria eradication, 1955-1970; for smallpox control, 1955-1958; and for smallpox eradication, 1959-1970 (thousands of US\$)

This includes disbursements under the regular effective working budget, the technical assistance component of UNDP, the Voluntary Fund for Health Promotion and other funds administered by WHO, including funds in trust, Revolving Sales Fund, Real Estate Fund, etc. It does not include bilateral aid.<sup>c</sup> 1955 was the first year of the global malaria eradication programme; 1959 was the first year of the global smallpox eradication programme; 1967 was the first year of the Intensified Smallpox Eradication Programme.

with drugs. Traditional methods of mosquito control, such as the drainage and larviciding of breeding sites, were rarely used; nor was the need foreseen for research to identify alternative control measures. It was believed that the tools needed for eradication were available; the problem was the administrative one of applying them properly. Thus, for each country, a highly elaborate plan of operations was developed which included the use of standardized and detailed manuals. National plans varied little from country to country. They called for *preparatory*, *attack*, *consolidation* and *maintenance* phases—terms which many persons were later to apply to stages of the smallpox eradication programme.

In summary, during the *preparatory* phase, information was collected on malaria prevalence and vector bionomics, detailed maps were prepared of all structures to be sprayed, houses were numbered, supplies were procured and personnel were recruited and trained. During the *attack* phase, lasting 3-5 years, insecticide spraying teams sprayed the

interior walls of all buildings semi-annually with DDT, working block by block and house by house. Late in this phase, case detection was begun by surveillance agents, who visited each house at monthly intervals to take diagnostic blood samples from anyone who had had fever during the preceding month. Presumptive drug treatment was given and additional spraying conducted when infected foci were detected. When the malaria rate fell below 1 case per 1000 persons, the *consolidation* phase began, during which routine spraying was halted and intensive surveillance was conducted to detect the few remaining cases, who were then treated, while any residual foci were eliminated by further spraying. The *maintenance* phase commenced when there had been no evidence of malaria transmission for 3 years. Only in this final phase, expected to be reached within 6-10 years, would the established health services of the country play a role. So detailed and specific were the plans that special manuals were prepared to define explicitly the terminology to be used.

Until 1966, the malaria campaign made steady progress, at least when viewed from a global perspective (Fig. 9.1; Scholtens et al., 1972). Of the total population living in malarious areas in 1959, 26% lived in maintenance- or consolidation-phase areas; by 1966, this proportion had risen to 59%. Most of the progress, however, was made in countries in which rapid economic development was taking place or in which year-round vector breeding did not occur. In other areas, progress was generally less than anticipated, and the financial resources required to sustain unexpectedly protracted attack and consolidation phases of the campaign were far greater than had been foreseen.

By 1966, government authorities and donors alike had become increasingly concerned about the programme's progress and apprehensive about its future. The WHO Expert Committee on Malaria, in its thirteenth report, did not dispel these anxieties. In an analysis of 42 programmes, the Expert Committee reported that in 12, satisfactory progress was being made; in 22, progress was slow and corrective measures had been delayed or were inadequate; and in 8, such measures had been ineffective or had not been

taken at all (WHO Expert Committee on Malaria, 1967).

In 1967, the Director-General was requested by the Twentieth World Health Assembly in resolution WHA20.14 to study how best to re-examine the global strategy and to report back. His report in 1969 documented a litany of operational, technical, planning and budgetary problems and concluded that:

"The present methods of eradication... are still laborious and often too expensive for the limited resources of developing countries. Unless the present methodology is further simplified, global malaria eradication, though theoretically possible, will continue to be beyond reach for many years to come." (World Health Organization, 1969b.)

A revised strategy called for malaria control where and when eradication could not be achieved quickly. Global eradication remained the ultimate goal, however, and the responsible division in WHO continued to be called the Division of Malaria Eradication. The principal donors, UNICEF and the United States Agency for International Development (AID), viewed the situation otherwise, and between 1970 and 1973, phased out their support. Dr Perez Yekutieli identifies 1973 as the year that marked the end of the global malaria eradication programme (Yekutieli, 1981).

A fundamental weakness in the strategy had been its almost total reliance on the use of residual DDT within the framework of a rigidly defined, meticulously executed programme. However, as Dr Scholtens and his colleagues (1972) pointed out:

"There is now wide recognition and acceptance of the limitations of short-term national malaria eradication efforts based on residual insecticides... The use of diverse anti-malarial measures has been strongly recommended, but the development of these has been inhibited for a decade because of high expectations from the eradication effort... These developments are further complicated by the diminishing number of 'mariologists' and proliferation of 'eradicationists'."

In brief, research on alternative strategies had been seriously neglected (Farid, 1980). Jeffery (1976) pointedly observed:

"The science of malaria control, developed slowly and painfully from the beginning of the century to a relatively high state of sophistication, was almost overnight converted to the rather simplistic technology of malaria eradication, which basically

Fig. 9.1. Percentage of population in malarious areas, by phase of campaign, 1961-1970. In 1970, the total population of the malarious areas was 180 631 000. (Source: Scholtens et al., 1972, and WHO data.)

required that one know how to deliver 2 grams of something to every square metre of a sometimes elusive interior wall, and to manage a hopefully ever-diminishing Kardex file of cases."

As many individuals wryly noted, the programme was far more successful in eradicating malariologists than malaria (McGregor, 1984).

As is apparent from this brief account, the proposal by the USSR in 1958 for a global smallpox eradication programme coincided with the initial thrust in the development of the global malaria eradication programme. Substantial resources for that programme continued to be both needed and provided throughout the early 1970s. During this period, interest in, and support for, yet another eradication programme was understandably less than enthusiastic. During the mid- to late 1960s, as the increasing difficulties in executing the malaria programme became evident, confidence in the technical judgement and administrative competence of WHO steadily eroded. Not surprisingly, this was reflected in attitudes towards, and support for, smallpox eradication on the part of potential donor agencies, both international and national, as well as those in the endemic countries. Although some of the people concerned with malaria eradication were later to attribute the demise of that programme to the diversion of attention and resources to smallpox eradication in 1967 (Farid, 1980), it is apparent that the malaria eradication effort was by then already in serious difficulty.

Nevertheless, the malaria eradication programme indirectly made major contributions to the development of the successful Intensified Smallpox Eradication Programme by demonstrating the fallacy of two premises. The first was that, given a highly effective control measure, the problem was simply to apply it correctly. For this reason, and contrary to the practice in malaria eradication, WHO smallpox eradication programme staff actively promoted a gamut of research activities which indeed proved crucial to its success. The second premise was that rigidly standardized procedures, uniformly applied throughout all the countries concerned, could be successful. Thus, in the smallpox eradication programme, principles, rather than a detailed methodology, were stressed, and programme staff were encouraged to adapt their programmes to local conditions, to learn from

experience and continually to modify their methods. Not surprisingly, programmes in the different countries varied significantly from one another, and a cadre of experienced smallpox epidemiologists proliferated and matured.

The malaria eradication services themselves, with spraymen and surveillance agents regularly visiting every house, might well have contributed significantly to smallpox eradication through their participation in case detection and vaccination. However, as described in later chapters dealing with field operations, in all but a few countries these services refused to undertake any activities except those concerned with malaria. Indeed, in Ethiopia, malaria staff successfully blocked the development of the smallpox eradication programme until 1971.

### *The yaws programme*

Apart from the global programme for malaria eradication and the *Aedes aegypti* eradication programme in the Americas, the only other commitment to disease eradication by an international organization before 1959 pertained to yaws. A resolution committing the Pan American Sanitary Bureau to yaws eradication followed successful yaws control field trials in 1948-1949 in Haiti, long a highly endemic area. This stemmed from the discovery that a single injection of long-acting penicillin provided a cure for this disease, which primarily affects people living under crowded, poverty-ridden conditions in the rural tropics of Asia, Africa and South America. It is caused by a spirochaete, *Treponema pertenue*, which is transmitted by direct, non-sexual contact from person to person, and produces chronic, deforming, and incapacitating lesions. In 1948, UNICEF and WHO began to provide support for mass treatment programmes for syphilis and other treponematoses such as yaws (Guthe, 1960), and over the succeeding decade supplies and equipment worth more than US\$9 million were made available to 61 countries and territories. In the yaws eradication programmes, individual patients were diagnosed by inspection and given penicillin, or, where the disease was widespread, the entire population was treated. The results were immediate and dramatic, but the elimination of the disease from an entire area required repeated visits to ensure that all cases had been cured. If any remained after the campaign had ended,

the disease resumed its spread. Occasional latent infections and patients who subsequently relapsed were especially troublesome.

Although a commitment to global eradication was never made by the World Health Assembly, the WHO Expert Committee on Venereal Infections and Treponematoses (1960) recommended that "there should be no delay by health administrations in extending the campaign for the world-wide eradication of yaws and endemic syphilis which is a feasible undertaking from a technical point of view". Programmes designed to achieve country-wide eradication were launched in the mid-1950s in 49 countries and were remarkably successful in controlling yaws; however, the disease was eliminated in only a few of the smaller countries (Yekutieli, 1981). Evaluations revealed far more low-level persistent infection and transmission than had been originally supposed and by 1966-1967 the term eradication was no longer applied. Even in the Americas, in which regional eradication was the stated objective, the programme was not vigorously supported and Haiti itself never became completely free of yaws.

#### *Programmes for the eradication of other diseases*

The possibility of eradicating a number of human diseases was actively debated in many different forums from 1947 onwards. Such discussions, however, effectively ended in 1966, at about the time that the Intensified Smallpox Eradication Programme was established, and simultaneously with an increasing awareness that none of WHO's regional or global programmes offered much hope of success. In the USA, the term eradication and the concept were examined and discussed with regard to several other diseases. In 1961, the Surgeon General of the United States Public Health Service established a special task force "to evaluate present efforts to control syphilis and to recommend principles and methods that will make it possible to establish a timetable leading to the eradication of syphilis as a public health problem" (Hinman, 1966). The task force, more circumspect, recommended a programme to "eliminate syphilis as a public health hazard in the United States", but little came of this. The idea of eradicating tuberculosis was more forcefully pursued, first with Dr J. E. Perkins (1959) and then with Dr Soper (1962) arguing that a global programme should be

undertaken. Dr Soper took the same view about tuberculosis as he had about other diseases—namely, that the problem was fundamentally one of political commitment and public health administration. The Surgeon General, in 1963, established a task force to examine this problem as well, but its report provided no blueprint for eradication (Hinman, 1966).

During the 1960s, the basic concept of eradication increasingly fell into disrepute. One of the last of the papers to advocate it was that by Dr Soper entitled "Rehabilitation of the eradication concept in prevention of communicable diseases" (Soper, 1965). Most persons accepted the views of the widely read Dr René Dubos, who eloquently described for layman and scientist alike the intricate adaptive relationships, evolved over time, between man and microorganisms. One of his books, *Man Adapting*, published just before the advent of the Intensified Smallpox Eradication Programme, concludes that eradication programmes "will eventually become a curiosity item on library shelves, just as have all social utopias".

Following the success of the smallpox eradication programme, however, the concept of eradication again came under examination, and although some scientists waxed enthusiastic about the prospects of eradicating other human diseases (Stetten, 1980)—notably, poliomyelitis, measles (Hopkins et al., 1982), yaws (Hopkins, 1976) and dracunculiasis (Hopkins, 1983b)—others, who had themselves been intimately involved with earlier eradication programmes, concluded that there were no suitable candidate diseases for global eradication in the immediate future (Henderson, 1981; Yekutieli, 1981). Nevertheless, in view of the unexpectedly rapid progress that had been made in the control of poliomyelitis in the Americas, the Directing Council of the Pan American Health Organization accepted in 1985 a "proposal for action" for the eradication of poliomyelitis from the Americas by 1990. The following year, in 1986, the Twenty-ninth World Health Assembly endorsed efforts to eliminate dracunculiasis "country by country, in association with the International Water Supply and Sanitation Decade" (World Health Organization, 1987). The resolution (WHA39.21) of the Health Assembly refers to "eliminating" the disease, but it is difficult to distinguish this from the notion of eradication (see Chapter 31).

### Eradiation as Viewed by a Distinguished Scientist

"Eradiation in its most exacting sense, namely as applied to the whole world, is not merely an armchair game of epidemiologists; it has become the official policy of several national and international organizations.

"At first sight, the decision to eradicate certain microbial diseases appears to constitute but one more step forward in the development of the control policies initiated by the great sanitarians of the nineteenth century, which have been greatly expanded since the beginning of the microbiological era. In reality, however, eradication involves a new biological philosophy. It implies that it is possible and desirable to get rid of certain disease problems of infection by eliminating completely the etiological agents, once and for all...

"In all cases the problems posed by the biological and epidemiological peculiarities of each type of infection are still further complicated by financial, administrative and political uncertainties. Even if genuine eradication of a pathogen or vector on a worldwide scale were theoretically and practically possible, the enormous effort required for reaching the goal would probably make the attempt economically and humanly unwise...

The popular appeal and fervid ring of the word eradication is no substitute for a searching analysis of the manner in which limited supplies of resources and technical skills can best be applied for the greatest social good...

"Social considerations, in fact, make it probably useless to discuss the theoretical flaws and technical difficulties of eradication programs, because more earthy factors will certainly bring them soon to a gentle and silent death. Certain unpleasant but universal human traits will put impassable stumbling blocks on the road to eradication. For example, it is easy to write laws for compulsory vaccination against smallpox, but in most parts of the world people would much rather buy the vaccination certificate than take the vaccine; and they shall always find physicians willing to satisfy their request for a small fee...

"Public health administrators, like social planners, have to compromise with the limitations of human nature. For this reason, and many others, eradication programs will eventually become a curiosity item on library shelves, just as have all social utopias." (From *Man Adapting*, by Dr René Dubos, 1965.)

### WHO SMALLPOX CONTROL AND ERADICATION ACTIVITIES, 1946-1958

#### Introduction

Prior to 1959, when the Twelfth World Health Assembly decided to undertake smallpox eradication, the only cooperative international effort to control smallpox was a WHO regional programme to eradicate it in the Americas. That programme, begun in 1950, was not vigorously promoted and, by 1959, was progressing far more slowly than had been hoped (Pan American Health Organization, 1959).

It may seem curious that smallpox was not identified by WHO as the initial target for eradication, if indeed the objective of disease eradication was to be pursued at all. Smallpox, after all, could easily be prevented by vaccination, and many industrialized countries as

well as some developing ones had demonstrated the feasibility of interrupting transmission over large areas encompassing several countries. Because of the frequency of importations, the disease was of concern to all countries and vaccination was extensively practised. Even as late as the 1970s, smallpox vaccine was the only vaccine widely used throughout the world. For tropical areas, a heat-stable freeze-dried preparation was available, although not widely used (see Chapter 7). It was recognized that the disease was spread through close personal contact and that there was no known animal reservoir. Transmission by insect vectors, if it occurred at all, was of no significance.

The control and eventual eradication of smallpox depended in large part on the effective vaccination of large numbers of people. This was a much simpler operation than the more complex and costly vector control measures needed, for example, for the

eradication of yellow fever or malaria, and was much easier than trying to treat all cases of a disease—the basic strategy employed in yaws and hookworm eradication programmes.

As has been noted, however, the historical roots of human disease eradication programmes go back to Dr Gorgas' successful elimination of yellow fever from Cuba and Panama—basically a vector control programme—followed by the Rockefeller Foundation's yellow fever eradication programme. When this was unsuccessful, the objective of *Aedes aegypti* eradication was pursued throughout Brazil and subsequently other Latin American countries. During this time, too, recently introduced infestations of *Anopheles gambiae* in Brazil and Egypt were eliminated. All these activities involved the allocation of large resources to vector control. The question of eradicating smallpox did not arise, perhaps in part because most of those concerned with the eradication concept worked in Brazil and the USA, in which the mild form of the disease, variola minor, prevailed—an illness of marginal public health importance; and perhaps in part because smallpox was then so widespread.

During and immediately after the Second World War, the all but miraculous effect of DDT in destroying insect vectors of disease promised an ultimate solution to the serious problem of malaria. Senior staff of WHO and of the national health services in many countries had been initiated into public health work either in pre-war vector control programmes (principally in the Americas) or in post-war malaria control programmes, and this was where their interest lay. The promise of DDT was still to be explored—a new and exciting venture, incomparably more attractive than endeavouring to apply more widely a vaccine that had been in use for 150 years in the control of a disease that, owing to importations, continued to recur everywhere.

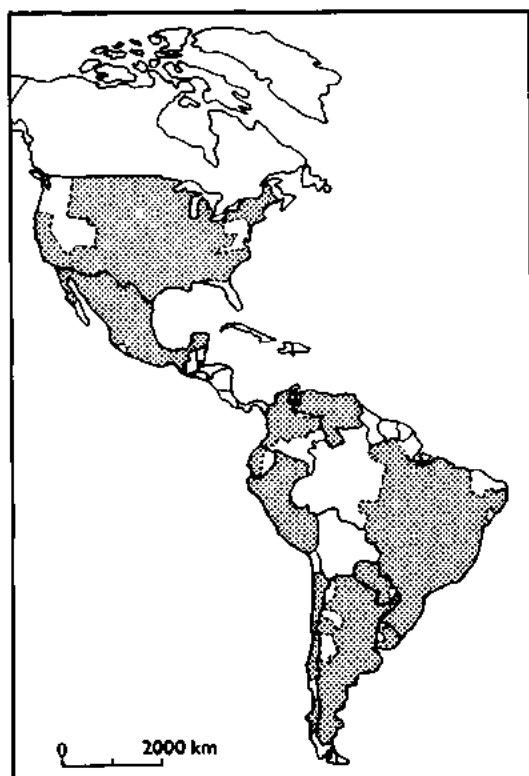

The decision, in 1959, to commit WHO to the global eradication of smallpox represented for the World Health Assembly a marked departure in its attitude towards this disease. Before this time, the Health Assembly resolutions had cautiously urged only improved programmes for smallpox control; for example, in 1954, in resolution WHA7.5, it had requested the Director-General "to provide within budgetary limitations the assistance requested by national administrations to further their smallpox control pro-

grammes" (World Health Organization, 1973a). During this period, the Organization's activities pertaining to smallpox had been concerned primarily with the implementation of the International Sanitary Regulations, the technology required for the preparation of a suitable freeze-dried vaccine, and the development of vaccine standards which might be adopted internationally (see Chapter 7).

### Smallpox Eradication in the Region of the Americas

In the Region of the Americas, WHO's interest in smallpox had been greater than in its five other regions. The countries of that region, on the recommendation of the Regional Director, Dr Soper, had unanimously agreed in 1950, at the XIII Pan American Sanitary Conference, to undertake a regional programme for the eradication of smallpox, a disease which was described in the Director's report as being widespread throughout the Americas at that time. In Fig. 9.2, which identifies administrative subdivisions in the region that reported 1 case or more during a 3-year period, the problem appears to be far more extensive than it really was. In the USA, for example, cases were almost all of the mild variola minor type; no state reported more than a few cases, and almost none of them was confirmed as smallpox by the state health authorities. Whatever the true extent of the problem, the delegates were sufficiently persuaded to decide on a regional eradication programme, and in 1952 they voted to allocate US\$75 000 to the programme; an additional subvention of US\$144 000 was made available in 1954.

The ability and inclination of the Region of the Americas to adopt policies dissimilar to those of the Organization as a whole is partly explained by the fact that this region historically had a somewhat different relationship to WHO from that of the other regions, being rather more independent and having additional financial resources. When, in 1946, an International Health Conference had drawn up the WHO Constitution, it had been envisaged that regional organizations then in existence would become an integral part of WHO and, specifically, that the Pan American Sanitary Bureau (PASB) would be integrated as soon as possible. PASB, then only a small organization with few staff, had been in

"SMALLPOX: This map is... prepared on the basis of routine reports received at PASB. It shows the States, Departments or Provinces where one or more cases of the disease were reported [between January 1947 and May 1950]. It is very probable that some of the shaded areas may have had only a few cases of smallpox and that these may have been infected in other areas.

"No reports were received from Bolivia where smallpox is known to occur. Smallpox cases in Cuba, Panama, Trinidad and the Chilean epidemic, were of imported origin. No cases were reported in Haiti, Dominican Republic, Costa Rica, El Salvador and Honduras...

"No distinction has been made between smallpox and alastrim." (Pan American Sanitary Organization, 1950b.)

Fig. 9.2. States, departments or provinces of countries in the Americas that reported smallpox cases to the Pan American Sanitary Bureau, January 1947 to May 1950.

existence, under one name or another, since 1902 (see Chapter 12). Its primary concern, like that of several other regional health bodies, had been to formulate agreements relating to the quarantinable diseases and to oversee their implementation (Howard-Jones, 1980). However, in January 1947, at the XII Pan American Sanitary Conference, the delegates emphasized the separate identity of PASB by constituting the Pan American Sanitary Organization (PASO; the name was changed in 1958 to the Pan American Health Organization, or PAHO) with PASB as its headquarters and secretariat. Nine months later, at the first meeting of its Directing Council, it authorized its Executive Committee to negotiate with WHO on condition that "the Pan American Sanitary Organization should continue to function as an independent entity for the solution of problems of a continental character" (Pan American Sanitary Organization, 1950a). In April 1949, Dr Brock Chisholm, Director-General of WHO, and Dr Soper, the Director of PASB, signed a formal agreement which recognized PASO as

an "independent entity" which could carry out and finance its own programmes in the Western Hemisphere provided that they were "compatible with the policy and programmes" of WHO (Howard-Jones, 1980). PASB was funded thereafter from two sources: funds provided through WHO from the assessed contributions of its Member States and additional funds contributed by Member countries of PASO, the largest contributor being the USA. With proportionately more funds than WHO and with a forceful director committed to the concept of eradication, PASO embarked on a regional smallpox eradication programme in 1950, in addition to the other eradication programmes already described.

Until 1947, Dr Soper had personally exhibited little interest in smallpox (Soper, 1965). That year an outbreak of 9 cases occurred in New York City, introduced by a visitor arriving by bus from Mexico (Weinstein, 1947). To control the outbreak, an ill-advised, chaotic, month-long mass vaccination campaign had been launched during which 6.3

million persons were vaccinated, 6 of whom died from complications of vaccination (Greenberg, 1948). Dr Soper, learning that thermostable freeze-dried vaccine was being produced in Europe, recognized that such a vaccine might make it possible to eradicate smallpox in the Americas. Moreover, in the light of the recent turmoil of the New York City outbreak, an eradication programme could be seen to be of significant benefit to PASO's largest contributor, the USA. The programme would also serve to demonstrate the value of PASO as an international health agency of relevance to all Member countries in a way that programmes of little significance to the USA, such as those for the eradication of yaws, yellow fever and malaria, would not. As Dr Soper noted: "The point is too often missed by public health administrators that theirs is a selling as well as an administrative job" (Soper, 1965).

Dr Soper sought help from the United States National Institutes of Health in developing the techniques for preparing freeze-dried smallpox vaccine and was referred to Mr William Gebhardt at the Michigan State Health Department Laboratory. By 1950, studies on a new freeze-dried vaccine, prepared by Mr Gebhardt, commenced in Peru under the direction of a new PASB staff member, Dr Abraham Horwitz, later to become Dr Soper's successor. The results were excellent and soon thereafter Mr Gebhardt, supported by PASB, assisted laboratories in other countries of the Americas in preparing the vaccine. Arrangements were made to have it tested at a laboratory in Denmark, although this was seldom done (Pan American Health Organization, 1966). PASB offered technical assistance to some countries but, as noted in the Director's annual report for 1957 (Pan American Sanitary Organization, 1958): "The Bureau did not have the funds nor the appetite for joining in the intensive vaccination campaigns that have so often given temporary relief, but became interested rather in improving the tools and methods through which permanent eradication might be brought about." Thus, responsibility for the execution of national programmes and for their cost was left essentially to the respective governments. From available records, it would appear that the programmes in the various countries differed widely in quality; vaccinal immunity after mass campaigns was seldom assessed and little was done to improve the reporting of smallpox cases. The

Director, in his annual report for 1958 (Pan American Health Organization, 1959), characterized the programme "as advancing at a slower rate than had been anticipated" and noted that "the disease is still an important public health problem in the Americas". Nevertheless, by the end of 1958, smallpox transmission appeared to have been, or to be on the verge of being, interrupted in all the countries of the Americas except Brazil, Colombia and Ecuador (see Chapter 12).

Up to 1966, the amounts spent annually by PAHO on smallpox eradication never exceeded US\$75 000 (Table 9.4). The investment was modest in relation to the results obtained.

### An Abortive Attempt to Launch a Global Smallpox Eradication Programme, 1953

At the World Health Assembly, the eradication of smallpox was discussed for the first time in 1953. The Constitution of WHO states in Article 2(g) that one of the functions of the Organization is "to stimulate and advance work to eradicate epidemic, endemic and other diseases". Citing this article, Dr Chisholm, then serving his last year as WHO's first Director-General, presented a special report entitled "Further action on general world health problems" (document EB11/63; unpublished) to the eleventh session of the Executive Board in February 1953 and then to the Sixth World Health Assembly in May. The report states:

"The first four years of work by WHO have shown its programmes developing in practice into two almost distinctive groups. Firstly there are the

essential programmes of general international character, many of them traditional... [such as]... quarantine, statistical and standardization of drugs... Secondly, there are the advisory services provided directly to individual governments...

"Inevitably the form of the advisory services in the first phase has been determined almost entirely by local needs... Originally the Interim Commission and the Health Assembly... visualized that the Health Assembly would define true world programmes into which the country requests would be incorporated."

Dr Chisholm noted that a general, direct, practical world programme would demonstrate "the importance WHO has for every Member State" and also its role "not only through the necessary and valuable present form of direct assistance to governments, but also by concerted international action". He took note of the smallpox eradication programme in the Americas and advanced the argument that an appropriate subject of general concern should be selected for a world-wide campaign—specifically, smallpox eradication. A 5-year budget providing approximately US\$131 000 per year was proposed.

The proposal was not enthusiastically received. Delegates from Australia, Belgium, El Salvador, India, Pakistan, South Africa, the United Kingdom, the USA and Venezuela all expressed views to the effect that the problem of smallpox was really a regional or even local one, and that insufficient knowledge was available. Summarizing, the delegate of the United Kingdom pointed out that the problem was vast and complicated and it did not appear that a world-wide machinery for such a campaign was suitable at this time. He pointed out that, "Such a campaign might prove uneconomical and would not... add to the prestige of the Organization" (World Health Organization, 1953). He put forward a resolution which read, in part:

"In view of the many political, economic and social factors that must be considered,

REQUESTS the Executive Board to further study [the matter] and to report to the Seventh World Health Assembly."

The delegate of France offered an alternative resolution which stated, *inter alia*:

"Approves in principle the suggestion of the Director-General that WHO should encourage certain world-wide programmes."

This was rejected, and a somewhat amended version of the United Kingdom draft was adopted as resolution WHA6.18 (World Health Organization, 1973a).

Each of the regional committees was asked to discuss the proposal but, except in the Americas, none expressed enthusiasm and, at the Seventh World Health Assembly in 1954, the proposal was deferred pending further study. Later that year, the newly elected Director-General, Dr Marcolino Candau, sent a letter to all Member States offering advice and assistance, if required, in the execution of smallpox control programmes and requested replies. In his report (document A8/P&B/7; unpublished) to the Eighth World Health Assembly in 1955 Dr Candau said that the replies received indicated that most countries "do not desire any immediate practical assistance in the control of smallpox. A small number would welcome technical advice and assistance, mainly in connection with the production of reliable [freeze-]dried vaccine. Only two requests were made for consultant services". The concept of a global programme for smallpox eradication was thereupon quietly buried. In that same year, however, the proposal to adopt a policy of

WHO, c 1950

**Plate 9.5.** Brock Chisholm (1896–1971), the first Director-General of WHO, 1948–1953, proposed to the World Health Assembly in 1953 that a programme of global smallpox eradication should be undertaken by WHO. Considered then by delegates to be too "vast and complicated", the initiative was rejected, not to be reconsidered until 1958. Meanwhile, a programme was started in 1955 for the global eradication of malaria.

global malaria eradication was advanced and delegates urged that it should be undertaken as a matter of the highest priority. The programme, which was vastly more costly and complex than smallpox eradication and whose feasibility was far more questionable, was adopted virtually without dissent.

Not until the USSR returned to active participation in WHO and Professor Zhdanov presented its proposal was the subject of smallpox eradication again raised. Although the decision in 1959 to embark on a global eradication campaign might appear to have been a logical extension of the regional eradication programme in the Americas, it was not. Professor Zhdanov himself was unaware of the regional initiative and it was not mentioned in debate either at the Executive Board sessions or at the World Health Assemblies of 1958 and 1959, nor was it noted in the Director-General's reports. It was a regional programme which, by 1958, had been largely forgotten, even by delegates of the countries of the Americas.

## THE SMALLPOX ERADICATION PROGRAMME, 1959-1966

### Introduction

Seven years had elapsed between the decision of the Twelfth World Health Assembly (1959) to undertake global smallpox eradication and that of the Nineteenth World Health Assembly (1966) to allocate significant funds from the regular budget of the Organization to enable an intensified campaign to be conducted. Progress during this period was far slower than had been anticipated in the Health Assembly resolution WHA11.54. During the period 1959-1966, malaria eradication was WHO's largest programme and its principal preoccupation, and this was no less true even for many Member States in which smallpox was endemic, because malaria was also present in most of them. WHO allocated some funds for smallpox eradication, intercountry meetings were held to discuss programme execution and methods of vaccine production, and letters were sent periodically by the Director-General appealing to Member countries for voluntary donations of vaccine. Few such donations were received. The USSR, under bilateral agreements, provided large quantities of vaccine to India, as well as to a number of other countries, and the USA provided

bilateral support to several smallpox eradication programmes, including those of Bolivia, India and Iran, but on the whole enthusiasm for smallpox eradication was lacking.

Greater interest in the programme began to be shown when a series of events led the USA, in 1965, to commit itself to providing assistance to a regional smallpox eradication programme in western and central Africa, and to begin to support more enthusiastically the programme for global smallpox eradication. The USSR, impatient with the inadequacy of a programme in which it rightly took a proprietary interest, eagerly welcomed this change in attitude. In concert with other delegations, it requested the Director-General, in 1965, to prepare a proposed programme and budget for an intensified campaign. In 1966, this was approved together with a designated financial commitment of US\$2.4 million from the regular budget. Preparations thereupon started for an Intensified Smallpox Eradication Programme to begin in January 1967.

### Status of Smallpox, 1959

In 1959, 63 countries or territories officially reported to WHO a total of 77 555 cases of smallpox. When national records were reviewed and revised by WHO in the late 1960s, the total for 1959 was increased to 96 571 cases but, whatever the figures, reporting was recognized to be incomplete, though the degree of underreporting was not known. Some countries provided no reports despite the stipulations of the International Sanitary Regulations; in other countries, including large ones with comparatively well-developed health systems, the only cases reported were those hospitalized in the larger cities.

No attempt was made in 1959 to distinguish between countries in which smallpox was endemic and those in which the only cases were imported ones; in preparing this chapter, however, we have tried to determine the probable situation in 1959, based on information now available (Fig. 9.3 and Tables 9.5 and 9.6). To facilitate comparison with the situation in the period 1967-1977, the designations of countries and territories as they existed in 1977 are used. From the records, it is probable that smallpox was endemic in 1959 in 59 countries and territories in Africa, South America and Asia, which

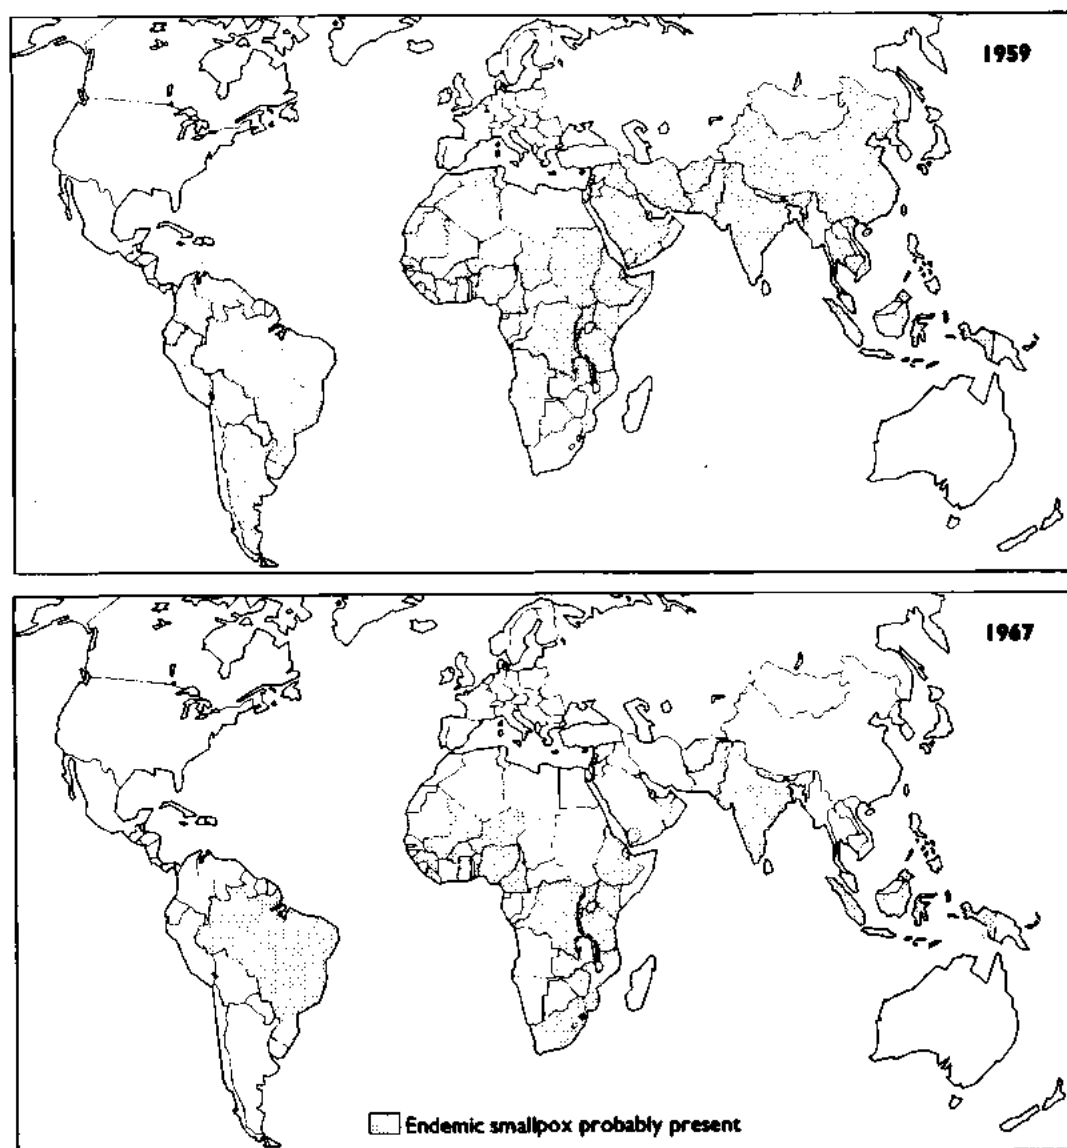

Fig. 9.3. Countries and territories in which smallpox was believed to be endemic, 1959 and 1967.

then had a total population of 1 734 921 000. Together, these countries constituted a substantial proportion of the land area of the 3 continents concerned and included 59% of the world's population. It is important to note, however, that in 1959 endemic transmission was on the verge of interruption in a number of Asian countries (Cambodia (Democratic Kampuchea), China, Iraq, Malaysia, Saudi Arabia, Thailand and Viet Nam) and in Africa (Algeria and Angola). Transmission appears to have been interrupted in all these countries over the period 1959–1962.

### The Global Eradication Programme Begins, 1959

The Director-General's proposed programme, as presented to the Twelfth World Health Assembly in 1959, envisaged national campaigns in which at least 80% of the population of each country would be vaccinated or revaccinated. Responsibility would rest primarily with individual governments, which would be expected to bear the major burden of programme administration and execution as well as of cost (World Health

Table 9.5. Countries and territories believed to have endemic smallpox, 1959 and 1967: summary by continent

Organization, 1959b). WHO would be responsible primarily for providing technical assistance when requested and fellowships for the training of staff, as well as for assisting in the development of vaccine production. Little was said about a leadership role for WHO in overall planning or in coordinating the campaign. Since delegates to the 1954 Health Assembly and most regional committees had so forcefully argued the case that smallpox was a local or regional matter, this approach was understandable. Moreover, malaria eradication then commanded whatever discretionary resources were available.

### Budgetary Provision for the Programme

The annual expenditure of funds for smallpox eradication between 1959 and 1966 by WHO, PAHO and the United Nations Expanded Programme of Technical Assistance is shown in Table 9.7. Between 1960 and 1965, the annual expenditure by WHO and PAHO ranged from US\$76 118 to US\$188 351, increasing in 1966 to US\$374 544, primarily because of a large disbursement of funds by PAHO for supplies for Brazil. Donations of vaccine averaged US\$120 000 per year from 1960 to 1966, and UNICEF provided almost US\$250 000 during this period for vaccine production equipment. Overall, however, the expenditure for smallpox eradication amounted to only 0.6% of the total expenditure of funds placed at the disposal of WHO between 1960 and 1966 and to 0.2% of the regular budget in the same period (see Table 9.3).

Every year the Director-General reported to the Health Assembly that progress in the smallpox eradication programme was slow, the principal obstacle being identified as the lack of funds for vehicles, supplies and equipment. The Health Assembly regularly urged that a larger budget should be provided for smallpox eradication and, when this was not done, finally requested the Director-General, in resolution WHA17.43 in 1964, to provide "under the future regular programme and budget of the Organization—if necessary at the expense of lower-priority activities—for making good the shortfall of the vaccine required, and of other essential supplies and equipment..." (World Health Organization, 1973a). Apparently, there were few activities of lower priority because the Director-General's proposed budget for 1966 provided for less than US\$200 000.

### Programme Activities, 1959-1962

Responsibility for coordinating the programme was assigned to a newly recruited medical officer, with a secretary, who were for several years WHO's only full-time employees working on smallpox eradication. The medical officer worked as one of several in the Virus Diseases unit of the Division of Communicable Diseases. For comparison, there were 5 professional staff at Headquarters in the Leprosy unit and 28 in the Division of Malaria Eradication. There were no staff members in any of the WHO regional offices solely responsible for smallpox eradication and, until 1966, only 5 full-time WHO

smallpox eradication advisers were assigned to field programmes—in Liberia, from 1962; Bolivia, from 1963; Afghanistan, from 1964; and Kenya and Mali, from 1965. A WHO adviser served in a part-time capacity in Nepal from 1962. The total population of these countries was less than 40 million. None of the programmes made significant progress, although Bolivia, in which there were no cases of smallpox when the adviser was assigned, remained free of the disease.

Soon after the programme began, inter-regional conferences were held in Africa (1959) and in Asia (1960) to discuss methods of conducting smallpox eradication programmes, and training courses in the techniques of producing freeze-dried vaccine were held in Nigeria (1960) and Thailand (1961). The medical officer from WHO

Headquarters visited a number of countries, on request, to discuss the possible implementation of programmes, but it was apparent that few countries were in a position to do much unless additional resources could be made available.

From 1959 onwards, the Director-General, at the request of the World Health Assembly, presented each year a formal report on the programme for discussion by the delegates. Beginning in 1961, the tenor of the discussions and the resolutions reflected increasing impatience. At the Fourteenth World Health Assembly (February 1961), the comments of a delegate of the USSR, Dr V. N. Butrov, were reported as follows:

"It seemed . . . that WHO and its regional offices were not giving the problem all the attention that

it deserved... [In] the Annual Report for 1960, for example, the chapter on the Eastern Mediterranean Region was the only one where the matter was dealt with at all seriously. The chapter on South-East Asia... and the chapters on Africa and the Americas did not contain any reference to smallpox." (World Health Organization, 1961.)

A delegate of Peru, Dr Carlos Quirós, was no less concerned; he noted that "the proposed programme and budget estimates failed to show any specific allocation for that work [smallpox eradication]". At that time, the budget document, as presented to the delegates, identified project budgets in each country and region, but the amount to be spent by WHO Headquarters on smallpox eradication was not specified as such nor was a table provided to summarize expenditures by categorical programmes. Dr Quirós intro-

duced a resolution calling for a specific budget allocation, arguing that "WHO should not merely give assistance to governments for smallpox eradication but should give it as part of a well-defined global eradication programme like the programme that existed in the case of malaria". The Director-General discouraged such a move, explaining that he did not see what purpose it would serve. The resolution ultimately passed (WHA14.40) stated only that "... it is urgent to speed up the activities of the programme..." but, for the first time, the Health Assembly specifically called for "voluntary contributions in cash or in kind" from Member States, an appeal which was thereafter renewed annually.

During the first few months of 1962, 13 imported outbreaks occurred in Europe, a fact

pointedly reported to the Fifteenth World Health Assembly by the Director-General. Despite the obvious problem which smallpox constituted for non-endemic countries, he observed that the Organization had received to date only 34 million doses of vaccine, of which 25 million were from the USSR. His report acknowledged that progress was poor, and he estimated that only US\$10 million in external assistance should suffice to achieve eradication. A delegate of the USSR, Dr S. S. Marennikova, renewed the appeal for smallpox eradication to be given a special allocation in the budget and expressed regret that the Organization had "not availed itself of all

the offers made by the Soviet Union to provide specialists—in vaccination, research, etc." In reply, Dr P. M. Kaul, an Assistant Director-General, observed that there was not so much a lack of expert knowledge "... the real difficulty was in providing sufficient vaccinators and in the organization of campaigns, an administrative point in which there was not a marked need for experts" (World Health Organization, 1962). In fact, WHO then had little notion of what was really needed, a point stressed by several delegates and reflected in the resolution adopted (WHA15.53), which called on the Director-General to compile for all countries

WHO, c. 1968

**Plate 9.6.** Marcolino G. Candau (1911-1983), the second Director-General of WHO, 1953-1973, was largely preoccupied with the difficult and costly task of the global eradication of malaria throughout his tenure. The programme, started in 1955, began to experience serious problems in the mid-1960s and was transformed into a control programme in the early 1970s. The global smallpox eradication programme began and was intensified during his period of office.

their "requirements and firm estimates of costs for their smallpox eradication programmes".

### Proposed Provision of Support through the WHO Regular Budget, 1963

By the time the Sixteenth World Health Assembly was convened, in May 1963, 4 years had elapsed since WHO had committed itself to global smallpox eradication, but there was still little progress to report and little substantive information available that would permit a better estimate to be made of total needs. With prodding from Professor Zhdanov at the preceding Executive Board session, WHO made its first attempt to define which countries were endemic and which were not. The Director-General's report (World Health Organization, 1963b) concluded that there were then thought to be 44 endemic countries, of which 14 were conducting eradication programmes, 22 had programmes on paper but were not yet implementing them, and 8 had so far done nothing at all. As Professor Zhdanov pointed out, "WHO was

far from having done everything possible" and urgently requested that priority should be given to the programme. "It was, perhaps, the only programme that could really be completed, and in the foreseeable future" (World Health Organization, 1963c). A summary table showing the proposed allocations for smallpox eradication was presented for the first time, but, as a delegate of the USA, Dr C. L. Williams, observed, this amounted to a mere US\$227 100 for the whole of 1964. Reasoning that if only US\$10 million were required in external assistance, and this over a 5-year period, he expressed the belief that funding should be provided from the regular budget so as not to have to wait for voluntary contributions. This position was supported by a number of other delegates. Dr Kaul, responding on behalf of the Director-General, argued that "the Organization was giving as much encouragement as possible; the reasons for slow progress were mainly to be found at the national level where administrative difficulties and grave material shortages had to be overcome". He added that "further [voluntary] contributions had been received recently and it was hoped that it would be possible to meet all the requirements for vaccine from that source" (World Health Organization, 1963c).

Support for a special budget, financed through assessments of Member States, was growing, but the Director-General resisted the idea. The malaria eradication programme was already recognized to be in trouble, thus endangering WHO's credibility. The provision of a special budget for smallpox eradication implied that WHO was taking primary responsibility for promoting and coordinating yet a second eradication effort. In his view, the prospects for its success were not good. It was then believed, as stated in reports prepared by WHO staff, that eradication could be achieved only if at least 80% of the population were vaccinated. From Dr Candau's own experience in working in Brazil, he knew this to be impossible in the vast Amazon region, and there were unquestionably other areas in other parts of the world in which similar difficulties would arise.

Dr Kaul's optimistic statement to the Health Assembly in 1963 regarding contributions was surprising, since, in fact, few voluntary contributions were then being received. India, at the time of the Sixteenth World Health Assembly, was desperately short of vaccine. The country had embarked

### Problems of WHO Support for Smallpox Eradication in India, 1963

"At present in this Region, there are only two directly assisted smallpox projects ... Except for a nominal amount of \$100, no amount is provided for supplies and equipment for the Nepal project ... [For Afghanistan] we are providing \$5000 in 1963 and a sum of \$12 000 for ... 1964 and 1965 for supplies and equipment. We are certainly prepared and anxious to give further assistance in smallpox eradication in our Region. However, under the existing budget provisions only marginal activities described above can be carried out.

"This brings me to the case of the Indian programme which is the largest and most important in the whole world ... In pursuance of the Assembly and Board discussions, SEARO has been promising the government in giving them every help in procuring more supplies of dry vaccine to meet their total needs for their mass programme. The government now wants to know very cogently as to how WHO is going to help them ...

"In your memorandum of 13 March you have explained to me how the Director-General's circular letter of 31 July has brought practically no response for free gifts of vaccine, vehicles and other equipment. For WHO this is a very unsatisfactory position ... One thing is certain and that is this—having once pushed a government into a vast programme of this size and a programme which has importance globally much more than nationally, any failure of this magnificent national effort would fall substantially at the door of the WHO, if not legally, at least morally."

(Extracts from a letter from the Director of the WHO Regional Office for South-East Asia to Dr P. M. Kaul, WHO Assistant Director-General, dated 4 April 1963.)

on an ambitious national mass vaccination programme, with substantial support in national currency from the USA and a bilateral gift of approximately 100 million doses of vaccine per annum from the USSR. Nevertheless, the quantity of vaccine available was far from sufficient. Indeed, shortly after the Health Assembly concluded, the Director-General made emergency appeals for vaccine for India to help to meet a projected deficit of 50–100 million doses a year. Few countries, however, had the laboratory capacity to make more than token contributions even if they were so inclined.

### Voluntary Contributions

Although letters asking for contributions to the programme were sent each year by the Director-General to all countries and to UNICEF, few responded (Table 9.8). UNICEF had provided substantial support for malaria eradication and was not prepared to support another eradication programme. Mr Maurice Pate, the Executive Director, in a letter of 11 July 1962 to Dr Candau stated: "As a general policy, UNICEF has not been prepared to give assistance to a separate mass campaign for smallpox vaccination but we are quite willing to contribute to countries who

wish to incorporate smallpox vaccination as a function of their public health services." As a consequence, UNICEF's contributions to the programme remained small and were intended primarily for the purchase of equipment for the production of vaccine.

Up to the end of 1963, only US\$7880 in cash had been contributed to the Special Account for Smallpox Eradication and 32 million doses of freeze-dried vaccine of which 25 million came from the USSR and 2 million from the Netherlands. An additional 3 million doses of liquid vaccine were contributed by Jordan and 2 million by Mexico. Twenty-eight million doses had been distributed, but this was much less than what was needed. The problem was, in part, administrative (see Chapter 11). Samples from each lot of vaccine proposed for donation had first to be examined in a WHO reference laboratory to ensure that the lot met the requisite standards of potency and purity. Within WHO, the receipt and dispatch of samples were the duty of the unit dealing with biological standards, a small unit which was not otherwise concerned with the smallpox eradication programme. The reference laboratory, in turn, tested the specimens only when a sufficient number had accumulated to make it worth while. As a result, it was not uncommon for there to be a delay of 6–18 months between the receipt of

Portugal	?	Results of tests awaited
Switzerland	2 325 000	Vaccine satisfactory; donation accepted
Tunisia	1 000 000	Results of tests awaited
United Arab Republic (Egypt)	800 000	Vaccine not satisfactory
United Kingdom	4 000 000	Vaccine satisfactory; donation accepted
Yugoslavia	1 000 000	Samples awaited

<sup>a</sup> Designations of countries used at the time.

<sup>b</sup> Although the Japanese donation was accepted, its receipt is not recorded in WHO documents; its value has therefore not been shown in Table 9.8.

samples and the notification of results. Even when the results were found to be satisfactory, further delays occurred, often of many weeks' duration, because of problems in arranging for the shipment of the vaccine. The delays in testing were sometimes so long that the production laboratory sent the lots concerned to other consumers and the whole process had to be repeated.

In response to the Director-General's emergency appeal of June 1963, a number of pledges of vaccine were made, the status of which in February 1965 (Table 9.9) illustrates some of the problems of vaccine supply at that time.

A total of 15 countries had pledged some 15 million doses of vaccine but 18 months later, as Table 9.9 shows, only about 6.6 million doses from 4 countries had been accepted, far short of the anticipated requirement of 50 million doses for India alone for 1 year.

### The First WHO Expert Committee on Smallpox, 1964

Whatever the urgency conveyed in resolutions adopted by the Health Assembly, WHO took no additional measures to strengthen the smallpox eradication programme. The medical officer originally assigned to work on smallpox left the Organization in June 1963 and his responsibilities

were transferred to another staff member, who dealt with smallpox only on a part-time basis.

In January 1964, WHO decided to convene an Expert Committee on Smallpox to discuss the problem. The Committee, in its report (WHO Expert Committee on Smallpox, 1964), carefully noted that the Director-General had been requested in 1959 "to prepare a programme of advice and help to countries on the basis that campaigns would be primarily the responsibility of national governments". Nothing is said in the report of the progress or lack of progress made. Although the Committee viewed the eradication of smallpox as feasible, its recommendations did not propose a substantially more responsible role for WHO, as is evident from its report:

"The success of the smallpox eradication programme within a reasonable period of time is directly linked on the one hand with the amount of practical assistance in the form of technical advice and the supply of vaccine and other essentials which the smallpox-free countries are prepared to give to the endemic countries, and on the other with the efforts which the endemic countries are prepared to put into the setting-up of effective programmes on a national or regional basis.

"The Committee's principal recommendation is that WHO should take all steps in its power to increase the international co-operation so that the success of the programme will be ensured in the shortest possible time."

The Committee's report discussed at length various aspects of the virology and immunology of smallpox and vaccinia, the steps to be taken in the conduct of a mass vaccination campaign, and other technical matters. In the execution of programmes, *preparatory*, *attack*, and *control* phases were described which resembled, in both terminology and strategy, those of malaria eradication. Following the *preparatory* phase, the entire population would be vaccinated during the *attack* phase, not unlike the corresponding phase in malaria eradication, during which all buildings were sprayed with DDT. After the completion of this phase, the *control* phase would begin, during which cases and outbreaks would be investigated and contained. The Committee placed its main emphasis on mass vaccination. It stated that vaccination of 80% or more of the estimated population had been found to be unsatisfactory in some cases and that "the target must be to cover 100% of the population". What the Committee had in mind was the situation in India, in which smallpox continued to occur in certain areas even though the number of vaccinations recorded was greater than 80% of the estimated population. The statement was made by the Committee despite the fact that assessment in India had already shown that unsuccessful vaccinations, repeat vaccinations of the same individuals and the falsification of reports on numbers of vaccinations performed meant that levels of vaccinal immunity were far lower than the reported 80% (see Chapter 15). Nevertheless, the Committee asserted that if success was to be achieved, the target must now be vaccination of the entire population. This conclusion only served to reinforce the Director-General's doubts about the feasibility of smallpox eradication.

The Committee said little about the reporting of smallpox, except to deplore its unreliability at that time and to urge that "countries in which notification of cases and deaths is defective should make an effort to effect improvements". No reference was made to the need for developing reporting systems or to surveillance and containment measures—both key factors in the post-1967 strategy.

### **The Seventeenth World Health Assembly, 1964**

At the Seventeenth World Health Assembly (1964), Dr Kaul introduced the

subject of smallpox eradication on behalf of the Director-General by stating: "The Expert Committee considered that the Organization's eradication programme had been well conceived and soundly based" (World Health Organization, 1964b), an opinion which was not expressed in the Committee's report. The principal problem, as seen by the Organization, was that of providing adequate quantities of freeze-dried vaccine. Dr Kaul pointed out that an emergency appeal for 30 million doses of vaccine, made immediately after the previous Health Assembly, had resulted in the receipt of only 7 million doses, all of which had been used.

Whatever the Expert Committee may have thought about the programme, delegates continued to express displeasure. Several pointed out that there had been no reduction in the number of reported cases between 1959 and 1963, that programmes were proceeding too slowly, and that it was time for WHO to assign priorities to its programmes and to prepare a definitive plan for the smallpox eradication programme, including provision for an adequate central and regional staff, estimates of needs and a specific time schedule (World Health Organization, 1964b). A resolution to this effect was submitted by the delegations of Australia, Chile, India, Liberia, the USSR and the USA, which, with some amendments, was adopted (resolution WHA17.43).

### **A Retrospective View of Progress in Smallpox Eradication, 1959-1964**

Although the Director-General, in his reports to the Health Assembly, had repeatedly observed that progress was slow and unsatisfactory, the information available to WHO regarding smallpox eradication programmes and on the numbers of cases throughout the world was fragmentary at best, and little effort had been made to obtain better information. Official telegraphic reports of cases were received by WHO in conformity with the International Sanitary Regulations, and a few countries provided descriptions of the programmes which they were undertaking. Reports on national programmes varied widely in quality, from highly optimistic ones containing few data to a very small number which described in detail where, and how many, vaccinations were being performed. Notifications, as the WHO

**Plate 9.7.** A display prepared for the WHO Regional Committee for South-East Asia in 1964. The strategy at that time focused wholly on vaccination and on achieving "100% coverage". No mention was made of the reporting of cases or the containment of outbreaks.

Expert Committee had noted, were "frequently unreliable" and "not accurate". Indeed, when reporting first began to be emphasized, WHO smallpox eradication staff estimated that not more than 5% of all cases were then being reported; later, it became apparent that the figure was closer to 1%.

Yet, more was achieved during the period 1959–1964 than was appreciated. The most significant progress was made in eastern Asia, notably the elimination of smallpox from China in 1961 or thereabouts. Had this

achievement been known and properly documented, it might have provided encouragement both to WHO and to the endemic countries. The People's Republic of China, however, did not become a Member of the Organization until 1973 and provided little information about either smallpox or its programme until 5 years later. From the incomplete reports available and the observations of visitors, it was believed that China had effectively brought smallpox under control, but not until 1978, when a WHO team

visited the country, were data made available confirming that transmission had been interrupted in the early 1960s. Also, in 1959, Cambodia (Democratic Kampuchea) and Viet Nam appear to have recorded their last endemic cases although, because of the increasingly intense fighting throughout the area, their true status was also uncertain for many years. Malaysia, in 1960, and Thailand, in 1962, also succeeded in interrupting transmission following intensive, well-executed vaccination campaigns. Thus, in the period between the beginning of the global programme in 1959 and 1964, 5 large countries in eastern Asia became free of smallpox.

In western Asia also, a contiguous group of countries eliminated endemic smallpox following special vaccination campaigns conducted with varying degrees of diligence: Iraq in 1959, Democratic Yemen in 1960, Saudi Arabia in 1961, and Iran in 1963. Smallpox was, however, periodically reintroduced into these countries and others bordering the Gulf by pilgrims and migrant workers from southern Asia.

In the Americas, the regional programme of eradication begun in 1950 was continued. Although it was neither vigorously promoted nor substantially supported by WHO, Bolivia and Paraguay interrupted transmission in 1960 and Ecuador in 1963. A set-back occurred in 1963, however, when Peru was reinfected by the spread of smallpox from the Amazon region of Brazil.

Throughout much of Africa, the status of smallpox between 1959 and 1964 was less certain than in other parts of the world. Many countries were then becoming independent, civil strife was common and newly established governments were preoccupied with other matters. Health problems were but one of many concerns, and, among the specific diseases, smallpox was usually given little attention except when epidemics occurred. In northern Africa, smallpox was probably not endemic in 1959 except in Algeria, in which a protracted civil war had been in progress. Algeria's last endemic cases, however, were recorded in 1961. South of the countries bordering the Mediterranean, endemic transmission ceased or diminished to low levels in a number of the former French colonies, in which freeze-dried vaccine produced in France had been extensively employed. As became apparent during the Intensified Programme (see Chapters 17, 19 and 20), a thermostable vaccine, when reasonably

widely applied in sparsely populated African countries, often served to interrupt transmission even where coverage was not uniformly high and surveillance was poor. Of the former French colonies, the Central African Republic, the Congo and Gabon appear to have become smallpox-free in 1955, 1954 and 1956, respectively; Mauritania interrupted transmission in 1962 and Senegal in 1963. The Gambia recorded its last endemic cases in 1966. In the sparsely populated countries of Djibouti and Somalia, endemic transmission ceased in 1959 and 1962 respectively, without special programmes. In Angola and the Sudan, freeze-dried vaccine was used in intensive vaccination campaigns, and those countries became free of smallpox in 1959 and 1962 respectively. However, because of the long, open borders between African countries and the generally inadequate health infrastructures, endemic smallpox recurred in Africa as a consequence of importations. Thus 3 contiguous countries—the Central African Republic, the Congo and Gabon—began again to experience epidemics of smallpox in 1961–1962, as did Lesotho, South Africa and Swaziland in 1960–1963.

Meanwhile, other countries, including Burma, Colombia, India, Pakistan and Peru, conducted major vaccination campaigns which were reported in generally optimistic terms.

When the situation is viewed in retrospect, it is evident that much was achieved by a number of countries during this period, despite the lack of external resources and despite inadequate health care structures in many of them and the use of the thermolabile liquid vaccine by most. These achievements were, however, largely unknown to WHO Headquarters staff, so that the Director-General's reports were perhaps more pessimistic than was warranted.

### **Events Leading to the Introduction of an Intensified Global Programme, 1965**

Interest in a more important role for WHO in global smallpox eradication began to increase within the WHO Secretariat in 1964 following the appointment of Dr Karel Raška as Director of the Division of Communicable Diseases. Dr Raška, a distinguished and determined epidemiologist from Czechoslovakia, believed that smallpox eradication was an attainable objective. As he wrote: "The in-

BY COURTESY OF D. SALMON, 1969

**Plate 9.8.** Karel Raška (b. 1909), a distinguished Czechoslovak epidemiologist, served as Director of the Division of Communicable Diseases in WHO Headquarters from 1963 to 1970. He was a staunch advocate within the Organization of global smallpox eradication, and played an important role in launching the Intensified Programme in 1967. He had previously been Director of the Institute of Epidemiology and Microbiology, in Prague, which contributed a number of the epidemiologists, including Jezek, who worked for the Intensified Programme.

creased expenditure on the smallpox eradication programme in developed countries would pay itself back within three years after the achievement of eradication" (Raška, 1966). Even this estimate, as it was later found, was conservative, but using this and other arguments, he was able to persuade the Director-General of the need to create a separate Smallpox Eradication unit. This was established early in 1965, although only one medical officer, Arita, and a secretary were provided to staff it.

Meanwhile, two developments in the USA provided impetus to establishing an intensified eradication programme: the development and demonstration of the jet injector for administering smallpox vaccine; and a commitment by the USA to provide technical and material support to the smallpox eradication programme. These events are summarized below and described in greater detail in Chapter 17.

#### *Development of the jet injector*

During 1964–1965, pilot field studies using the jet injector showed that it had

potential in facilitating mass vaccination campaigns. The device had been developed during the 1950s for administering vaccines and other biologicals by percutaneous inoculation. A piston propelled a measured quantity of vaccine through a narrow orifice under high pressure sufficient to penetrate the skin and enter the subcutaneous tissue (Hingson et al., 1963). The fitting of a reservoir of vaccine to the injector made it possible for 500 or more vaccinations to be performed before replenishment was necessary; as many as 1000 persons per hour could be vaccinated by this means. For mass vaccination campaigns, it offered unique advantages, but before it could be used with smallpox vaccine two basic problems had to be solved: to be effective, smallpox vaccine had to be inoculated intradermally rather than subcutaneously; and the only jet injector in the 1950s which was sufficiently sturdy for large-scale use was powered by electricity and therefore unsuitable for use in the field. In 1962, Mr Aaron Ismach of the United States Army Medical Equipment Research and Development Laboratories (Millar et al., 1969) developed a special nozzle which made it possible to inoculate vaccine intradermally, and, subsequently, staff of the Communicable Disease Center (CDC) in the USA demonstrated that the technique was safe and produced as high a proportion of successful vaccinations as that obtained by conventional techniques. The problem of the power supply was also solved when Mr Ismach developed a pedal-operated, hydraulically powered model. Early in 1965, Dr Millar and his colleagues in CDC (Millar et al., 1971), serving as PAHO consultants, demonstrated in a pilot study in Brazil that a vaccination campaign using the jet injector required far less manpower than, and cost only one-third as much as, a campaign in which conventional techniques were used (see Chapters 11 and 12). Although this instrument eventually proved less useful than was initially expected, its advent stimulated the undertaking of mass vaccination campaigns.

#### *The commitment of the USA*

Further impetus was given to global smallpox eradication when, in 1965, the USA, WHO's largest contributor, began actively to support the eradication concept and in November of that year offered to provide technical and material assistance for smallpox

eradication and measles control programmes in 18 (eventually 20) contiguous western and central African countries (Gelfand & Henderson, 1966). The background to this initiative is of interest. Support by the USA for large-scale health programmes, other than those for malaria eradication and family planning, was a departure from its bilateral assistance policy at that time. The commitment to smallpox eradication emerged as a consequence of two unrelated factors: the need for a United States initiative as a demonstration of support for International Cooperation Year, a celebration of the 20th anniversary of the United Nations; and a developing regional programme, supported by the USA, for measles vaccination in western and central Africa.

United States involvement in providing measles vaccine to countries in western and central Africa began in 1961, when staff of the National Institutes of Health (Meyer et al., 1964a) demonstrated in a small study in Upper Volta (now Burkina Faso) that the new attenuated Edmonston strain of measles virus was both safe and efficacious. This was followed, at Upper Volta's request, by a country-wide measles vaccination campaign and, subsequently, by programmes supported by the United States Agency for International Development (AID) in other countries in the area (Henderson, 1967). The programme proved to be popular and, by 1965, at the request of governments in western and central Africa, AID had agreed to provide assistance to 11 of them. In the same year, CDC was approached and asked to provide the requisite technical assistance.

To Henderson, then on the staff of CDC, and his colleagues, the measles control programme made little sense, since it would inevitably be too difficult and costly for the countries concerned to sustain when bilateral assistance ceased. A regional programme for the eradication of smallpox, however, appeared to be feasible and to offer the possibility of achieving permanence. However, the control of smallpox, let alone its eradication, had not previously been considered by AID staff. Meanwhile, in a speech on 10 June 1964, the President of the United States, Lyndon Johnson, took public notice of the vaccination campaign in western Africa when he promised a new initiative in support of International Cooperation Year, stating: "I intend to dedicate this year to finding new techniques for making man's knowledge serve man's welfare... I intend to expand our

efforts to provide protection against disease." He then alluded to the measles vaccination programme in western Africa and continued: "We will expand our efforts to prevent and to control disease on every continent."

That the United States commitment might apply to smallpox did not emerge until World Health Day of the following year—7 April 1965. World Health Day, which commemorates the day the WHO Constitution entered into force in 1947, has a different theme each year. In 1965 "Smallpox Alert" had been selected as a result of many smallpox importations into Europe in 1962–1963, the intention being to stress the need for vigilance. Dr Benjamin Blood and Dr James Watt of the United States Public Health Service proposed a special presidential message for that day, committing the USA to supporting global smallpox eradication as an answer to the need for continuing vigilance against importations. Although no action was taken, a second opportunity to obtain a presidential commitment arose a month later in conjunction with the expected debate on smallpox eradication at the Eighteenth World Health Assembly. This time they were successful in persuading the staff of the President of the USA to issue a special press release: "President Johnson announced today that he has instructed the U.S. Delegation at the World Health Assembly to pledge American support for an international program to eradicate smallpox completely from the earth within the next decade." United States support was envisaged as the "contribution of technical personnel and other resources to the Pan American Health Organization..." and "assisting in the establishment of laboratory facilities in the developing countries to help meet requirements of vaccine".

Two months after this press release, CDC proposed to AID that a regional smallpox eradication measles control programme should be established throughout western and central Africa. This was a far more extensive and costly enterprise than the more geographically limited measles vaccination campaign envisaged by AID, and quite different from the type of assistance pledged by the delegation of the USA in its statement at the World Health Assembly. The President's staff, however, on learning of the proposed plan, expressed support and, on 23 November 1965, a press release was issued which began:

"Plans for campaigns to protect 105 million people from smallpox and measles in 18 African

countries were announced today by the White House. . . AID and PHS staff are beginning consultations with African and WHO officials on plans for the campaign, its acceptability to African countries and their willingness to contribute to the program."

What had begun as a field trial of a new measles vaccine in 1961 became a smallpox eradication-measles control effort involving 20 countries of western and central Africa (see Chapter 17, Fig. 17.1); in the process, the USA formally and strongly expressed its support for the global smallpox eradication programme.

### **The Eighteenth World Health Assembly, 1965**

At the request of the Seventeenth World Health Assembly, a comprehensive plan for a global eradication programme was presented by the Director-General at the Eighteenth World Health Assembly in May 1965 (World Health Organization, 1965b). Its preparation had been no easy task for the Secretariat, given the small number of staff assigned to smallpox eradication and the lack of information in Geneva about smallpox and smallpox eradication programmes throughout the world. To prepare the report, WHO recruited two consultants, Dr Frank Grant of Ghana and Dr P. M. Lal of India, to assist Arita. They were asked to review all available information and to visit 4 countries (Afghanistan, Burma, Mali and Nigeria) "to assess the situation and to reach some broad conclusions on the basis of a sample survey".

In his report (World Health Organization, 1965b), the Director-General expressed the belief that, so far as could be determined, 12 countries had succeeded in eradicating smallpox since 1959, but much more needed to be done. He concluded that:

(1) In many endemic countries, other health problems were considered to be of greater importance than smallpox.

(2) There was a need for, and frequent lack of, an adequate administrative and supervisory structure.

(3) Supplies of heat-stable freeze-dried vaccine in very large amounts and also transport, refrigeration and other equipment were needed, as well as short- and long-term consultants for the planning and execution of the campaigns.

(4) The maintenance phase (continuing vaccination) was as important as the attack phase if smallpox was to be prevented from recurring.

(5) Pilot projects were needed to determine strategy.

(6) Assessment of vaccination success rates by an independent team was vital.

(7) Contiguous endemic countries should start mass campaigns simultaneously.

The recommendations in the report dealt broadly with each of these points.

Introducing the report at the Health Assembly, Dr Kaul indicated that US\$80 million would be needed, an estimate which was based on the assumption that the entire population of the endemic countries would need to be vaccinated, at an average cost of US\$0.10 per vaccination (World Health Organization, 1965c). The estimate made no provision for the People's Republic of China, which, as previously noted, was not then a Member State of WHO. Of the total, US\$28 million were thought to be required from international sources—i.e., about US\$5 million a year for 6 years, rather than US\$10 million, as estimated in 1963.

Dr Kaul noted that a substantial increase in effort and in material support was essential if the eradication programme was to be speeded up and achieve its goal within a reasonable time. To strengthen the argument that additional voluntary contributions should be made by the smallpox-free industrialized countries, he pointedly drew attention to the costs associated with a recent importation into Sweden.

Delegates again indicated their dissatisfaction with the slow pace of progress, but more bluntly than before. A delegate of the USSR, Dr M. A. Akhmeteli, expressed the increasing irritation of his country, declaring:

"Malaria eradication seemed to have been the favourite daughter of WHO, whereas smallpox eradication seemed to have been treated rather as a foster child. . . criticism might have been averted if concrete measures had been included in the 1966 programme. . . The delegation of the USSR would support any concrete proposal for speeding up the programme, but it wished for a real programme." (World Health Organization, 1965c.)

Sir George Godber, of the United Kingdom, echoed these thoughts:

"... the Organization had been engaged in smallpox eradication for some seven years and . . . the programme had not met with as much success

as might have been possible. However, only WHO could get down to the root of the problem. It would be far preferable for WHO to concentrate upon smallpox eradication than to turn to some more ostentatious programme [a world health research centre then under consideration] which would lend only spurious prestige to the Organization ..."

Support for a WHO budget specifically for smallpox eradication was growing, but the USA in particular, although a promoter of smallpox eradication, was not in favour of this. Official government policy in the USA held that WHO should provide only technical assistance and advice; material support should be provided through other United Nations agencies and through bilateral and voluntary contributions to WHO. Accordingly, Dr Williams, of the United States delegation, introduced a resolution requesting the Director-General "to seek anew the necessary financial and other resources". This, of course, was what the Director-General had been asked to do by several preceding World Health Assemblies, and he had done so, but with little success. Potentially, one of the larger contributors was UNICEF, but Sir Herbert Broadley, on behalf of that organization, stated at the Health Assembly that UNICEF "would be unable to participate in a world-wide mass eradication campaign against smallpox, as it had done against malaria".

Although the resolution adopted at the Eighteenth World Health Assembly (WHA18.38) added little to what had already been said, its first operative paragraph expressed, more clearly than before, the attitude of the delegates:

"DECLARES the world-wide eradication of smallpox to be one of the major objectives of the Organization" (World Health Organization, 1973a).

### **A Special Budget for Smallpox Eradication, 1966**

The Director-General's position was a difficult one. If a more effective smallpox eradication programme were to be mounted, additional resources would be required, but it was apparent that voluntary contributions alone would not suffice. At the same time, malaria eradication was experiencing serious difficulties, for which additional resources

were also required. However, voluntary contributions for malaria eradication had diminished markedly, thus making substantial additional funds from WHO's regular budget necessary, if only to sustain the existing level of activities. The Director-General could propose a substantial increase in the Organization's budget to meet the additional requirements of an intensified smallpox eradication programme but that was certain to be met by strong objections, especially from the industrialized countries, which provided the bulk of the Organization's funds. The Director-General's proposed budget was debated each year by the Executive Board and Health Assembly but had regularly been accepted as presented. An unacceptable increase involved the risk that the proposed budget would be rejected and that a divisive debate would follow, an outcome which had so far been avoided.

The problem was resolved by presenting a proposal in two parts. The first was the regular budget allocation, which was increased each year to permit a modest growth in WHO's activities and to compensate for inflation. The second was for a special allocation of US\$2.4 million, which was identified as being explicitly for smallpox eradication; the Health Assembly could consider this separately and decide whether or not it was willing to commit these additional funds in support of the resolutions which it had adopted on smallpox eradication. If it was unwilling to do so, it would be apparent that delegates were less firmly committed to smallpox eradication than the Health Assembly's resolutions would suggest.

The allocation proposed for smallpox eradication may not now appear very large, but WHO's total budget at that time was itself not substantial. If both allocations were approved, it would mean an increase in the Organization's total budget of almost 22% and a comparable increase in the assessments of all Member States. Many countries could be expected to vote against the smallpox eradication budget: most of the industrialized countries, as a matter of policy, were opposed to substantial increases in the budgets of the United Nations specialized agencies; others, faced with difficulties in obtaining adequate amounts of convertible currencies to pay their assessments, would also object; and, finally, the smallpox-free developing countries that would not directly benefit from the programme could not be counted on for support.

Before presenting a new proposal to the Executive Board in January 1966, and then to the Nineteenth World Health Assembly in May of that year, the Director-General decided that another, more comprehensive, report should be prepared which would provide a detailed plan of action and more precise cost estimates. In September 1965, Henderson was asked by WHO to work with Arita, Dr Raška and Dr W. Charles Cockburn, chief of the Virus Diseases unit, in Geneva to prepare the document. Because accurate information on the status of programmes and the occurrence of smallpox was still largely lacking, this planning exercise was as speculative as earlier ones.

### **The Director-General's Report to the Nineteenth World Health Assembly**

The document prepared for presentation to the Executive Board in summary form, and to the Health Assembly in full (World Health Organization, 1966b), is of interest in that it sets forth the basic framework within which the Intensified Programme began to function. Conceptually, the programme differed from that for malaria eradication in three important ways: (1) principles for programme execution were provided rather than a highly prescriptive plan, in the belief that programmes would have to differ from country to country depending on resources, local conditions and the epidemiological situation; (2) a reporting system for cases was to be developed from the inception of the programme to serve as a guide in its execution rather than introducing such a system at the conclusion of an attack phase; and (3) research was to be encouraged in the belief that, whatever might be known about smallpox, more could be discovered which would facilitate its eradication. Projections of needs and proposals for the administrative structure represented a compromise between what Henderson and Arita considered necessary and what was acceptable to the Director-General.

#### *Strategy*

A basic strategy calling for systematic vaccination campaigns employing freeze-dried vaccine was retained. A new and important additional component was surveil-

lance—the notification and investigation of cases and their epidemiological characterization. This was an approach developed by Dr Alexander Langmuir at CDC (Langmuir, 1963), with whom Henderson had worked for the preceding decade. It had been applied in other disease control programmes in the USA, but appeared to be equally applicable to smallpox. Since this was the strategy which proved so important in the achievement of eradication, the relevant section of the Director-General's report is quoted here (World Health Organization, 1966b):

"It is necessary for the eradication programmes to develop a systematic plan for the detection of possible cases and concurrent investigation regarding the source and site of acquisition of the disease, the establishment of vaccination status and the prompt instigation of containment measures. Detailed epidemiological investigation of all cases to establish the reasons for their occurrence and the means by which they are being spread can be one of the most effective instruments to provide continuing guidance and direction in the vaccination programme. In the simplest terms, each case which occurs suggests the possibility of flaws in the programme. An outbreak, however small, demands a full critical review with appropriate revisions of the programme.

"The ultimate measure of any eradication programme is its success in reducing the number of cases to zero. So long as the disease is endemically transmitted, an eradication programme has failed to achieve its goal whatever the proportion of the population apparently successfully vaccinated.

"Even in countries with a limited local health structure, a systematic surveillance plan can and must be developed as an essential component of the eradication programme. The simplest type of approach might consist of a weekly report from each hospital and dispensary noting whether suspect cases of smallpox had or had not been seen. Simple basic information should be requested for each suspect case, consisting of name, age, sex, residence of patient and date of onset of illness. Hospitals or dispensaries failing to submit a report should be contacted promptly to ascertain specifically whether or not cases have been observed.

"This portion of the surveillance activity should be initiated concomitantly with the development of any systematic vaccination programme. Even where cases are comparatively few at the inception of the programme, detailed investigative and containment efforts should be initiated promptly. The discovery of apparent indigenous transmission should be accompanied by a two- or three-day intensive mass programme of vaccination in the

immediate area. In highly endemic countries, such detailed field appraisal may not be practical until a vaccination campaign in the immediate areas has been completed. It should not, however, be delayed until a country-wide programme has been completed...

"A regional surveillance programme is an important component part of the eradication scheme. Increasing facilities for travel plus continuing major population migrations across national borders permit ready dissemination of infection from country to country. Strengthening of the advisory staff at regional and national level to assist individual countries in the development of adequate surveillance programmes, able to render assistance promptly both in the field investigation phases and in direct containment operations and serving to integrate information obtained from the separate countries, would ensure greater success of the overall programme.

"It should be realized that the surveillance system thus being developed will be utilized not only for smallpox services but also to provide epidemiological services for other communicable diseases."

**Plate 9.9.** Alexander Duncan Langmuir (b. 1910), as director of the epidemiology programme at the Communicable Disease Center, Atlanta, GA, USA, from 1949 to 1970, developed the concept of surveillance and its application to the control of communicable diseases in the USA. This approach was introduced in 1967 in the Intensified Programme.

### *Status of smallpox*

The report defined the endemic countries at the end of 1965 as including 6 in Asia (Afghanistan, Burma, India, Indonesia, Nepal and Pakistan), 3 in South America (Brazil, Colombia and Peru) and essentially all African countries south of the Sahara. The cases officially reported to WHO in 1964 numbered just under 50 000; essentially the same number was reported in 1965, and this was not significantly different in magnitude from the 60 956 cases recorded in 1960. It was pointed out, however, that little credence could be given to these figures.

From what was known in WHO, few programmes were thought to be making substantial progress. Of 8 projects which were being assisted in some manner by WHO in Africa, only those in Côte d'Ivoire and Upper Volta were doing well. Liberia and Mali, which had received more assistance, had succeeded in vaccinating less than one-fifth and one-third of their populations, respectively, in 4 years; combined yaws control and smallpox vaccination projects in Nigeria, Sierra Leone and Togo were progressing very slowly; and a project in the Sudan, begun 2 years earlier, was considered unsatisfactory. In South America, only Peru was then taking effective measures. In Asia, mass vaccination campaigns had begun in Burma, India and Pakistan, but only Burma appeared to be making satisfactory progress. WHO-assisted projects in Afghanistan and Nepal were recognized as being in serious difficulty.

### *Overall programme*

An ambitious and, in retrospect, unduly optimistic programme was proposed which focused on the provision of support in 1967 to programmes already in operation and, in 1968, to the extension of the programmes to all other countries to be covered (Table 9.10); this made a total of 41 countries (as before, the People's Republic of China was not mentioned). The terms *preparatory*, *attack* and *maintenance* phases were used in the planning document but were later discarded when in practice they were found to be of little use. Thus, any comparison between projected and actual achievement is impossible to make.

It was expected that the programmes would differ from country to country, the vaccination campaigns in some being conducted in concert with other programmes by

local health staff, and in others by special teams. Vaccination by means of jet injectors, supplemented by multiple-pressure vaccination, was to be used in South America and Africa, but it was felt that prior evaluation

was necessary to determine whether jet injectors were suitable for use in Asia. The planning document stressed the need to ensure better vaccination coverage in the more densely populated areas and among

migrants but, wherever vaccination was performed, assessment of the results by independent teams was considered vital.

An "adequately staffed headquarters unit" of 3 medical officers was proposed, as well as the posting of a regional adviser in each of the 4 WHO regions in which endemic smallpox was present. International technical assistance personnel were expected to be required in most countries. Special emphasis was given to the need for regional staff "since the method of operations should be flexible enough to develop reasonably efficient programmes in the different epidemiological situations and health service structures in each country or area". The need for regional offices to assist in the establishment of regional surveillance systems was also noted in the document. It was proposed that funds should be provided for the development of vaccine production facilities, interregional training courses, consultants, fellowships, and necessary supplies and equipment.

### *Vaccine*

The plan called for 220 million persons to be vaccinated in 1967 (Table 9.11). Assuming, as the report did, that the South American countries and Pakistan produced sufficient vaccine for their own needs, and that the USSR would satisfy the needs of Afghanistan, Burma and India through bilateral assistance, enough vaccine would be available for 180

million persons. Much of the rest of the deficit was expected to be met if the United States programme in western and central Africa was implemented, since that would provide some 30-40 million doses each year.

### *Costs*

The overall cost estimates of the programme were based on crude approximations made, as before, by estimating the number to be vaccinated each year and multiplying by US\$0.10. The international assistance required was assumed to be about 30% of the total, comprising the costs of external technical assistance (vaccine, transport, supplies and equipment). Overall, an expenditure of US\$180 million was anticipated, of which US\$48.5 million from international sources would be required (Table 9.12). The totals were substantially greater than those estimated a year before—US\$80 million overall, with US\$28 million from international sources. For the first year, a WHO budget of US\$2.4 million was requested, or 36% of all external assistance required. The balance, it was hoped, would be made up by bilateral support or voluntary contributions. Although the estimates were rough at best and did not take inflation into account, it is worth noting that the international support ultimately provided between 1967 and 1979 (see Chapter 10, Table 10.8) amounted to approximately US\$98 million, twice the projected sum.

Table 9.11. Estimated number of smallpox vaccinations to be carried out with international assistance, 1967-1976; extracted from the Director-General's report to the Nineteenth World Health Assembly

### Problems With the Plan

The proposed plan was the outcome of a compromise between its authors and senior WHO staff, especially in regard to financial and administrative provisions. Senior WHO staff viewed the problem as being primarily that of providing adequate resources for mass vaccination and saw little need for either technical assistance or international coordination of efforts. Henderson and Arita, believing that the programme and particularly the concept of surveillance would be difficult to implement, saw the problem differently and expressed their concern as follows in a letter of 14 October 1965 to Dr Karel Raska, Director of the Division of Communicable Diseases (each problem proved to be as great as or greater than they foresaw):

"... certain fundamental principles are key ... adequate central guidance and direction must be provided which has sufficient authority to express itself through Regional Office levels to the individually responsible countries; adequate financing is mandatory; capable staff at all levels is requisite ... The programme, as revised, has a number of inherent weaknesses in each of these major areas:

"(1) *Central staff*—The proposed staff both at headquarters and at regional levels is ... far less than adequate to undertake the job ... the general scheme of the proposed programme is different from programmes of the past; surveillance techniques and their application are unknown in every one of the countries ... a substantial amount of training, guidance and assistance will be required from well-trained full-time staff within the Organization ... The relationship of the Regional Offices to the programme, central headquarters and country programmes should be carefully examined. Already we sense potential conflicts in policy with AMRO [Regional Office for the Americas], AFRO [Regional Office for Africa] and SEARO [Regional Office for South-East Asia].

"(2) *Financing*—More than half of the anticipated external budget for supplies and equipment must be forthcoming on some sort of volunteer basis from other international organizations or bilateral assistance programmes ... Voluntary contributions, however ... have been negligible ... In the light of recent past experience, we question whether this is sound ... we are still concerned that a maximum of flexibility in application of funds be maintained both within Regions and between Regions and between budget categories.

"(3) *Staff*—We gather there are major difficulties at this time in recruitment of competent staff ... The necessity of the headquarters and regional WHO smallpox staffs undertaking some responsibility in this regard should be recognized and central staff augmented accordingly ... Realistically, we suspect that the programme will be obliged to rely principally on comparatively junior medical officers who can be given intensive training and carefully supervised in their field work ... However, intermediate and senior level supervisory people would be requisite. They are not provided for under the revised proposal."

### Research

A statement that there was a need for continuing research on the epidemiology and virology of smallpox was inserted despite the objections of senior WHO staff, who believed, as they had with malaria, that enough was known about smallpox and that the only problems were the mobilization of resources and administration. To obtain agreement to include a section on research, a sentence had to be added: "It is hoped that total or partial financial support for many of these [research]

projects will be provided directly to the responsible investigators from national funds."

### The Discussions at the Executive Board (January 1966) and at the Nineteenth World Health Assembly (May 1966)

Dr Kaul introduced the Director-General's report at the Executive Board session in January 1966 and Mr Siegel described the

implications of a second appropriation for smallpox eradication. Dr Kaul noted that the Director-General, in his regular budget, had foreseen the need "to provide the impetus, direction, coordination and supervision on a global basis" and, accordingly, had proposed for 1967 the provision of US\$200 000 in the regular budget (World Health Organization, 1966a). This included both funds administered by WHO on behalf of the United Nations Expanded Programme of Technical Assistance and PAHO funds. Attention was not drawn to the fact that the amount proposed for smallpox eradication was actually the smallest since 1963. Mr Siegel introduced the special appropriation for smallpox eradication. WHO's effective working budget for 1966 had been US\$42 442 000; the corresponding figure proposed for 1967 was US\$47 242 000, an increase of 11.3% (World Health Organization, 1965d). Two possible figures for the appropriation for smallpox eradication were offered: US\$1 million and US\$2 415 000. If US\$1 million extra were provided for smallpox, the increase in the overall budget would be 13.7%; if US\$2 415 000 were provided, it would be 17.0%. Tables had been prepared showing the additional assessments for each country for additions to the regular budget of US\$1 million and US\$2 415 000. If US\$2 415 000 were provided, the additional cost for the smallpox programme for the USA, for example, would be US\$801 660; for Czechoslovakia, US\$25 440; and for the United Kingdom, US\$165 210. For purposes of comparison, the estimated annual costs of routine national vaccination activities, as determined at that time by those countries were: USA, US\$20 million (later studies revealed the amount to be almost US\$150 million), Czechoslovakia, US\$1 million, and the United Kingdom, US\$650 000. In the course of the debate, however, the fact was noted that the United Kingdom had spent US\$3.8 million to control imported outbreaks in 1962-1963.

After prolonged discussion the Executive Board agreed, in principle, to recommend to the Health Assembly the creation of a special appropriation for smallpox eradication in the regular budget, although most Board members expressed the belief that the amount allocated for smallpox eradication should probably be no more than US\$1 million, at least for the first year.

At the Nineteenth World Health Assembly (May 1966), the Director-General's report on

smallpox was presented to one of its two principal working committees, the Committee on Programme and Budget. There was, however, only a brief discussion before the Committee was required to resume a suspended debate on a draft resolution on malaria eradication, a resolution which deplored its slow rate of progress and actual regression in several countries. Before the debate could be resumed, the Committee took up the question of the overall WHO budget for 1967, the principal point at issue being the amount, if any, to be added for smallpox eradication.

The total budget figure under consideration by the Health Assembly, including funds for smallpox eradication, was US\$51 515 000, an increase, the Director-General said, of 15.8% over the corresponding level for 1966, including the supplementary estimates for that year (World Health Organization, 1966c). For purposes of comparison, it is useful to note what the assessments of certain countries would have been for a budget of this magnitude. The Financial Report for 1967 shows that in that year only 5 countries contributed 5% or more of the budget—USA, US\$16.6 million; USSR, US\$7.1 million; Federal Republic of Germany, US\$3.5 million; United Kingdom, US\$3.4 million; and France, US\$2.9 million—while 52 countries contributed the minimum amount, which that year was US\$21 320 (World Health Organization, 1968).

The developing countries, the principal recipients of the Organization's funds, usually argued for large increases in the budget; especially strong support for the smallpox eradication programme was voiced by delegates from the countries of western and central Africa, which had been promised assistance by the USA for a regional smallpox eradication-measles control programme. However, Professor E. J. Aujaleu, an eminent French government official and for many years a delegate of France, expressed a view frequently taken by delegates from most of the industrialized countries—namely, that the Organization's budget should not, in principle, increase faster than the average annual increase in the gross national product of its major contributors. He suggested that an overall increase in the budget of between 5% and 6% would have been more appropriate; other delegates proposed figures ranging from 4% to 8%. He and other delegates also suggested that the smallpox eradication pro-

Table 9.13. Nineteenth World Health Assembly, May 1966: results of votes on budget proposals

France	50 000 000	84	56	18	66	17
USA	50 415 000	90	60	36	54	7
Director-General	51 515 000	86	58	60	26	12

Source: World Health Organization (1966c).

programme might have an opportunity to become better established if a more modest beginning were to be made in 1967 and the programme expanded later. He proposed an overall budgetary ceiling of US\$50 million, with approximately US\$1 million earmarked for smallpox eradication. This proposal was supported by Canada, Italy, Turkey and the USSR. A compromise proposal was put forward by the USA, providing for a budgetary ceiling of US\$50.4 million, of which US\$1.4 million would be set aside for smallpox eradication. This proposal was supported by Australia, Austria, Belgium, the Federal Republic of Germany, Iraq, Japan, the Netherlands and Pakistan. Yugoslavia endorsed the United States proposal for a budgetary ceiling, provided that the full amount of US\$2 415 000 was allocated to smallpox eradication. Meanwhile, several countries indicated simply that they could not agree to the budget as proposed (Argentina, Czechoslovakia, Hungary, Poland, Romania and Venezuela); 19 developing countries, plus Finland, Norway, Sweden and Switzerland, spoke in favour of the Director-General's budget proposal. At the closure of the debate, successive votes were taken on the proposals advanced by France and the USA (Table 9.13), a two-thirds majority of Members present and voting being required for approval of the budget.

The proposals put forward by France and the USA were defeated, and a larger budget, providing all the requested funds for smallpox eradication, was accepted by a margin of 2 votes—the narrowest margin for the acceptance of a budget in the Organization's history. In perspective, the sum appropriated for smallpox eradication was not large, considering that programmes were expected to be conducted in 41 countries, thus providing an average allocation of less than US\$60 000 per country per year. However, the total sum accounted for 4.7% of WHO's total budget and was some 10 times greater than the sum allocated in the Organization's 1966 budget.

When the Committee on Programme and Budget resumed discussion of the proposed smallpox eradication programme, whose budget was now assured, delegates expressed their general support. In the course of the debate, Dr D. Venediktov, a delegate of the USSR, announced that his country would make a contribution of 25 million doses of vaccine each year for 3 years, a contribution which the USSR continued annually throughout the global programme; Dr Blood, a delegate of the USA, briefly described the commitment of the USA to programmes in western and central Africa; and additional assistance was promised by the League of Red Cross and Red Crescent Societies. The Director-General was requested to seek help from the World Food Programme, UNICEF and UNDP, as well as bilateral agencies. Although bilateral support was to play an important contributory role, relatively little assistance from other international organizations ever materialized.

The programme was thus accepted by the Health Assembly, albeit with less than unanimous conviction and commitment. Privately, many delegates were sceptical about the prospects for global eradication, although all were basically in agreement that better smallpox control would benefit both the countries in which smallpox was endemic and those subject to importations of the disease.

### Preparations for Initiating the Intensified Programme, 1966

By January 1966, when the Executive Board decided to recommend a special allocation for an intensified smallpox eradication programme, the global programme had been in progress for more than 6 years, but few WHO personnel had been assigned to it. The smallpox eradication staff consisted of a medical officer and a secretary in Geneva; 2 recently assigned African intercountry advisers, in Kenya and in Liberia; and 3 advisers assigned at country level, in Afghanistan,

Bolivia and Mali. With little known about the status of smallpox in the endemic countries or their prospective programmes or needs, major efforts were required to mount a fully fledged global programme capable of effectively utilizing the US\$2 415 000 provided in the budget.

In February 1966, immediately after the Executive Board session, the Director-General sent letters to each of the WHO regions indicating the possibility that additional funds specifically for smallpox eradication might be made available. Each region was requested to develop provisional plans for 1967-1968, based on a larger budget, and to identify their needs for vaccine, advisory personnel, supplies and equipment. In the Americas, a regional adviser was appointed, who immediately began discussions with the authorities in Brazil as well as with those of Argentina, Colombia, Ecuador and Peru, in which it was thought that programmes would be required.

Meanwhile, at CDC, Henderson was assembling staff, procuring equipment and working out plans with 16 countries of western and central Africa so as to permit programmes to begin there in January 1967 (see Chapter 17).

Late in May 1966, with the Health Assembly's formal approval of the programme and budget, activities steadily increased. Henderson was recruited to serve as chief of the Smallpox Eradication unit, a post he was to assume in November; a second medical officer, Dr Stephen Falkland, was temporarily assigned through transfer from another unit in WHO, and an administrative officer was assigned from the malaria programme. One or two consultants were recruited to visit countries in each of the 4 WHO regions in which smallpox was present to encourage them to develop national programmes.

Within the Organization, however, reservations about the wisdom of smallpox eradication were widespread and were reflected in administrative actions. The Director-General, in a meeting with regional directors immediately after the Health Assembly, privately expressed his doubts about the feasibility of eradication and cautioned them about imposing on countries a special programme like that for malaria eradication. As he saw the situation, the prospects for success depended on progress in the development of each country's basic health services. It was not

surprising, therefore, that a memorandum, dated 10 August 1966, was sent to all regional offices by two Assistant Directors-General, Dr Kaul and Dr John Karefa-Smart, which stated:

"The establishment of permanent basic health services should be given the highest priority since it is a prerequisite for the success of the smallpox eradication programme in any area and you should be prepared to consider providing from the smallpox eradication programme resources, such assistance as may be required for developing and strengthening basic health services in the area where the campaign is launched."

This policy statement effectively authorized the use of smallpox eradication funds to meet almost any of the all but inexhaustible needs of the basic health services.

In conformity with their belief that the smallpox eradication programme called for little more than the proper distribution of resources, senior WHO staff in July 1966 substantially reduced the Headquarters smallpox eradication budget. Funds for staff travel were reduced from US\$6400 to US\$2400, then sufficient to permit a total of approximately 3 trips of 21 days each; funds for consultants were cut so as to allow for only 3 man-months instead of 23; and funds for convening a meeting of a scientific group were cancelled. The research budget was reduced from US\$30 000 to US\$12 000 and responsibility for administering these funds was assigned to the Virus Diseases unit. Dr Raška vigorously objected to the changes and argued that travel funds should be increased to US\$14 000 and that a medical officer and 2 secretaries should be added to the personnel complement to create a unit staff of 7 (3 medical officers, an administrative officer, a technical assistant and 2 secretaries). The funds were eventually restored and the increase in personnel was approved when, in a meeting with the Director-General, Dr Kaul and Dr Raška, Henderson expressed doubt that he could manage a global programme of such magnitude without the resources stipulated and proposed to withdraw his candidature for the post of unit chief. Although that possibility was considered, Dr Raška eventually prevailed.

CDC staff, meanwhile, were working intensively to launch the AID-supported programme in western and central Africa. By the end of 1966, agreements had been signed with most of the countries concerned, a staff of 50 had been recruited and trained, operations

manuals had been prepared, and supplies and equipment had been procured. The CDC training programme concluded with an address, given by special invitation, by the Director-General of WHO and delivered by telephone on 31 August. His comments are noteworthy for two points. First, he stressed his concern that another special programme like that for malaria eradication might be developed: "You must jointly ensure that the smallpox eradication programme is a coordinated effort within the general health services of the country, and not a separate, isolated activity." Secondly, he stated: "The programme of eradication is planned over a period of 10 years", a goal which had been mentioned in the Health Assembly although not stated in the formal resolution. Uncertainty about the eventual outcome of the programme, however, subsequently led to instructions to omit any reference in official documents to the 10-year target date.

The attitudes of the WHO regional directors ranged from the interested, in the Americas (Dr A. Horwitz) and Eastern Mediterranean (Dr A. H. Taba), to the reluctant in the African Region, and to the frankly negative in the South-East Asia Region. In a letter to Dr Kaul (19 July 1966), the Director of the Regional Office for South-East Asia wrote: "In our view, on account of the organizational and administrative weakness of health services and serious socio-economic as well as financial difficulties, smallpox eradication is not likely to be achieved in the countries of this Region in the near future."

A programme which was rudimentary at best at the beginning of 1966 saw a quantum change in the level of activity by the end of the year. Henderson, Arita and Dr Falkland in the Headquarters unit were joined by Dr G. P. Nikolaevskij, a physician from the USSR, and Mr John Copland from the USA, who was to serve as the unit's administrative officer over the succeeding decade. Programmes in 16 countries of western Africa were about to commence; plans of operations had been signed with Brazil and the Democratic Republic of the Congo (Zaire); Dr Ehsan Shafa had been appointed Regional Adviser on Smallpox Eradication for the Eastern Mediterranean Region, and Dr Bichat Rodrigues in the same capacity for the Americas; and discussions had begun with a number of countries in the Eastern Mediterranean and South-East Asia Regions regarding eradication programmes.

Voluntary contributions to the programme during 1966 continued to reflect the general lack of interest among donors. Apart from vaccine donated by Switzerland, contributions in cash and in kind from Greece, Jordan, Kenya, Monaco, Nepal, the Netherlands, the Philippines, Thailand and Zaire were valued at only US\$17 632.

As the Intensified Programme commenced operations, however, the areas with endemic smallpox were actually substantially smaller than they had been in 1959 (see Table 9.6). The information now available indicates that in only 31 countries or territories, with a total population of 1 078 775 000, was smallpox endemic in early 1967, compared with 59 in 1959. Nevertheless, the problem remained formidable.

## SUMMARY

Since smallpox was such a good candidate for global eradication, it is surprising that the commitment to undertake such a programme was so long delayed and, even after being accepted by the World Health Assembly, so ill-supported both within WHO and by most Member States. In part, this derives from the historical roots of human disease eradication programmes originating, as they did, in vector control programmes, which continued and eventually culminated, in 1955, in the vast and costly global effort to eradicate malaria. Many of the leading figures in international public health during the 1960s had spent their formative years in vector control programmes, and it was with these that they were the most conversant and felt the most comfortable. Among the most important of the experts concerned were clearly Dr Soper, Director of the Pan American Sanitary Bureau for 12 years, and Dr Candau, Director-General of WHO for 20 years. Reluctance to undertake global smallpox eradication may also have originated, in part, from concern about the chances of such a programme being successful in Africa, where, in most areas, the transport, communications and health services infrastructures were poorly developed. Although malaria eradication had been undertaken with alacrity in 1955, and had been referred to as "global" in scope, Africa south of the Sahara had not been included in the programme. Perhaps of equal importance was an unstated acceptance of smallpox as an inevitable, entrenched disease

for which vaccination, a permanent feature of public health practice for more than a century, would always be required. Such, at least, was found to be the widely held belief, even after global eradication had been achieved and documented.

The first to call for regional smallpox eradication was the Pan American Sanitary Organization in 1950, and although its programme was reasonably successful as far as it went, it was not actively promoted or diligently pursued. In part, this reflected Dr Soper's preoccupation with eradication of the *Aedes aegypti* mosquito and, later, with malaria eradication. The lack of vigour can also be attributed to the fact that the largest endemic country was Brazil, in which the prevailing mild variola minor was not an important public health problem.

The proposal by the USSR in 1958 that a global programme to eradicate smallpox should be undertaken represented a new departure rather than, as some have believed, a logical extension of the regional programme in the Americas. Professor Zhdanov, the author of the proposal, reasoned correctly that smallpox eradication was a far more attainable objective than the eradication of malaria and that such a programme would benefit all countries, including his own, which shared a long border with endemic Asian countries.

Between 1959 and 1966, lack of interest on the part of WHO in smallpox eradication and the perceived lack of progress in the programme must be attributed, in large measure,

to WHO's preoccupation, as well as that of many Member States, with malaria eradication. Over this period, the persistent advocacy of smallpox eradication by the USSR in the World Health Assembly served to sustain interest in such a programme on the part of Member States, even though the Organization assigned few resources to it. Renewed interest in the programme was stimulated by the commitment of the USA in 1965 to support regional smallpox eradication programmes in a contiguous group of countries in western and central Africa, a decision which was less a product of rational policy analysis than a reluctantly accepted by-product of a regional measles vaccination campaign.

The decision by the World Health Assembly in 1966 to intensify the effort to eradicate smallpox was made with grave reservations. Eradication, as a concept in disease control, had largely been discredited, and the Director-General himself, believing smallpox eradication to be an unachievable objective, viewed the programme as one which could serve only further to undermine the Organization's credibility. Potential contributors to WHO's voluntary fund were demonstrably no more enthusiastic, and UNICEF, discouraged by the failure of the costly malaria eradication campaign, refused to support the programme as a matter of policy.

The Intensified Smallpox Eradication Programme was thus conceived in an atmosphere of sanguine rhetoric overshadowed by real doubts about its ultimate success.

## INTRODUCTION

The prevention and ultimately the eradication of smallpox constituted, in principle, one of the simplest and most straightforward of disease control activities. Effective long-term protection was provided by the single application of a vaccine which was easy to administer and highly stable even under tropical conditions. The presence of smallpox in an area could be readily detected because of the characteristic rash it produced, a rash which was readily identifiable by programme staff and villagers alike. Only patients with rash transmitted the infection to others, and then only to persons with whom they were in close contact. Because 10-14 days elapsed between each generation of cases, smallpox usually did not spread rapidly and epidemics took time to develop. Little more was required to control its spread than the isolation of the patient and the vaccination of his close contacts.

Despite the simplicity of both smallpox control and the strategy for its eradication, implementation of practical field programmes over a finite time span and on a global scale was a complex and difficult task. The achievement of eradication and its certification

ultimately required the cooperation of all countries. The participation of an international agency—the World Health Organization—was important, and probably essential, in ensuring such cooperation. As the international organization with technical responsibility for health programmes, WHO was requested by resolution WHA20.15 of the Twentieth World Health Assembly "to elaborate and implement the detailed plan, including the co-ordination of all international, bilateral and national efforts" for the Intensified Smallpox Eradication Programme (World Health Organization, 1973a). In carrying this out, however, WHO had no authority, other than that of moral suasion, to compel any country to initiate a programme, adhere to a plan or strategy, or contribute towards its support. For this reason, the global programme had to evolve within a framework of broad principles and expectations, pragmatically modified by reality, rather than within the confines of a comprehensive master plan having specific and enforceable time-limited goals.

In November 1967 the entire professional and secretarial staff of WHO throughout the world (including short-term consultants and

WHO agents in Zaire) numbered only 3302 persons, few indeed to cope with the array of tasks and responsibilities with which the Organization had been charged by the World Health Assembly, its governing body. Those assigned to smallpox eradication were likewise few in number, the staff of professional grade in no year comprising more than 150 persons (including consultants), of whom no more than 6 were in Headquarters and, at most, 7 in the WHO regional offices. They were expected to promote special programmes in more than 50 countries and to guide and coordinate activities which, at times, involved as many as 150 000 workers.

The programme presented unusual challenges for WHO, because the administrative structure and procedures of the Organization were primarily designed for the purpose of providing technical assistance, rather than material support, to a wide range of health projects in many different countries, few of which needed to be coordinated with others. Smallpox eradication, in contrast, required the provision of substantial material support and far closer collaboration among countries and among largely independent WHO regional offices, both in programme execution and in resource allocation.

The Director-General, Dr Marcolino Candau, had foreseen the need to mobilize substantial voluntary contributions in support of the programme but, in 1967, the Organization had had only limited experience and little success in obtaining contributions of this type. Significant donations for smallpox eradication—apart from some bilateral contributions—did not begin to be received by WHO until more than 7 years had elapsed. The consequent lack of resources constituted a serious, continuing problem and, even in the concluding years of the programme, those that were made available barely sufficed to sustain momentum. Donated vaccine, for example, was continually in short supply despite repeated appeals for assistance. The World Health Assembly was informed on a number of occasions of the need for additional funds, amounting to no more than a few million US dollars, and such funds were sought in correspondence and in meetings with potential donors, but the response was never adequate. Expenditures for smallpox eradication from WHO's own regular budget, measured in constant dollars, seldom exceeded US\$2.4 million annually, the amount initially appropriated by the Nine-

teenth World Health Assembly in 1966. Thus, restraint and compromise in field operations were necessary even when global eradication appeared imminent. Success was never a certainty even during the years immediately preceding the last known cases.

The problems of sustaining international commitment and support were formidable but no less so than those in many of the countries with endemic smallpox. Successful national programmes required a political commitment to undertake eradication, but smallpox was not a concern of high priority for some countries, even though they might have voted for World Health Assembly resolutions in favour of its eradication. Sustaining a commitment to the programme was no less difficult because, in many countries, governments changed frequently, as did the responsible health officials, and such changes led to the readjustment of national priorities. Famine, flood, epidemic cholera and the like often diverted smallpox eradication programme resources for long periods; civil war in Ethiopia, Nigeria, Pakistan and Uganda caused serious disruptions in operations; and collaboration with several governments in southern Africa, as well as some in Asia, was all but impossible owing to political constraints.

After smallpox had been eradicated, however, many persons inside and outside WHO mistakenly concluded that the achievement could be attributed to a generously financed, enthusiastically supported and authoritatively directed programme similar to a military campaign. That the programme had none of these characteristics is apparent from this and the succeeding chapters.

This chapter describes the context within which the programme functioned in WHO and how the overall campaign developed and matured, how national programmes were established, how international coordination was achieved, how personnel were recruited and budgetary problems resolved, how supplies of vaccine were obtained and handled, and how research contributed to the effort. All these activities were interrelated, and critical constraints or important developments in one area affected progress in others. For clarity of presentation, different elements of the Intensified Programme are discussed individually, beginning with the overall strategic plan and the programme's administrative structure, relationships and personnel at the international level. This is followed by a

description of the way in which national governments became committed to the programme. A discussion of resources, surveillance and research, from an international perspective, is followed by a general description of the approaches adopted and results obtained in national programmes of vaccination and surveillance. To provide an overall perspective and an introduction to the chapters describing national programmes (Chapters 12-23) and certification activities (Chapters 24-27), a brief chronological summary of events concludes the chapter.

### THE STRATEGIC PLAN

As described in the Director-General's report on smallpox eradication to the Nineteenth World Health Assembly (World Health Organization, 1966b), the strategic plan for eradication during the Intensified Programme was 2-pronged: (1) mass vaccination campaigns in which freeze-dried vaccine of assured quality was employed and which were assessed by special teams, and (2) the development of a surveillance system for the detection and investigation of cases and the containment of outbreaks. In the execution of the programme, 3 principles were considered to be of special importance: (1) all countries would need to participate and their efforts would require regional and global coordination; (2) flexibility and adaptability would be required in the implementation of national programmes; and (3) ongoing research, both in the field and in the laboratory, would be needed to evaluate progress, define alternative directions and methods, and solve problems as they arose.

To foster a common understanding of principles and procedures among a geographically far-flung programme staff, a comprehensive mimeographed manual entitled *Handbook for Smallpox Eradication Programmes in Endemic Areas*, hereafter referred to as the WHO Handbook, was issued by the Organization in July 1967 (SE/67.5 Rev. 1, World Health Organization). It was an elaboration and adaptation of a manual developed in 1966 for the programme supported by the USA in western and central Africa (see Chapter 17). The foreword to the WHO Handbook encouraged programme staff to innovate and to adapt as needed, since programmes should

evolve and change with experience. For this reason, the WHO Handbook was deliberately referred to as a "draft", in the expectation that revised versions would be prepared in subsequent years on the basis of field experience. Because of the small number of staff available in Geneva and the speed with which the programme developed, no revised version was ever issued, other means being used for passing on from one country to another new and important observations and approaches. The WHO Handbook included a wide variety of information, ranging from an account of the clinical features of smallpox and the methods used in laboratory diagnosis to a description of operational approaches for vaccination campaigns and surveillance programmes; it also described methods for use in health education, and the management of administrative and transport services. The Handbook concluded with a section describing more than 20 subjects of interest for field and laboratory research.

The basic strategy, with certain modifications in emphasis and subsequent elaboration of methods for its implementation, withstood the test of field experience. Vaccination campaigns, however conducted, were expected to reach at least 80% of the population in all areas, and higher, but unspecified, rates of coverage in the more densely populated cities and towns. The figure of 80% was not based on any epidemiological criterion, but represented what was believed to be an achievable goal in a well-conducted programme. As an indicator of the use of potent vaccine, the plan called for a take rate of at least 95% for primary vaccinations. To determine whether these objectives were being met in a given area, independent assessment teams were expected to monitor the results in a sample of the population soon after the campaign had concluded in that area.

Although assessments of coverage and take rates were considered to be important quality control measures in the vaccination campaigns, the WHO Handbook emphasized that "the success of the programme, therefore, is appraised ultimately by the occurrence or absence of endemic smallpox and the *principal assessment technique, accordingly, is surveillance*". Surveillance was to be based on a reporting system in which all existing medical and health units participated. This was to be supplemented by the immediate investigation of reported cases and a critical review of outbreaks to determine how and why small-

pox was being spread. The WHO Handbook stated that:

"... surveillance thus is an essential component of the programme since the term 'eradication' implies that the number of indigenous cases of smallpox is '0'. However extensive a country's vaccination campaign, however accurately assessed, a country with an inadequate system for surveillance cannot determine whether ... eradication has been achieved."

Since it was recognized that surveillance was a new concept and might be difficult to implement in highly endemic countries, a phased programme for its development was proposed (see Chapter 17, Table 17.4).

Mass vaccination was a familiar and readily acceptable concept to public health officials. Assessment of the quality of work and of progress, on the other hand, had not been common practice. Few were accustomed to measuring the success of their efforts and many, in fact, had never questioned whether the vaccine in use was satisfactory or had been properly stored. Both assessment and surveillance proved difficult to incorporate into most programmes.

### THE WORLD HEALTH ORGANIZATION

Among the international agencies, WHO has played a pre-eminent role and acquired substantial experience in providing technical assistance and cooperation for health programmes and in the development of international health policies. Other international agencies—e.g., UNICEF and the United Nations Development Programme—have provided substantial material assistance for health programmes, but WHO, from the time of its foundation, has seen its main task as that of providing technical guidance (Finkle & Crane, 1976). WHO, like all large administrations, has gradually evolved its own patterns and traditions of management and, while a full exposition of this subject is beyond the scope of this book, certain features are important to an understanding of the course of development of the global smallpox eradication programme.

In a comparative analysis of 8 major international organizations, Jacobson (1973) characterized the role of the Director-General of WHO as being unusually significant and influential. He described the Organi-

zation as a "strong and stable system", but noted that it was "dominated by the ideology of medicine" and "by a strong commitment to regionally decentralized service activities". Because of this decentralization of activities and responsibility within WHO, its regional directors have also played unusually important roles. They and the Director-General are the only elected officials of the Organization. If after a term of office of 4-5 years they wish to be reappointed, they must stand for re-election by Member States. The factor of re-election inevitably has a bearing on their decisions regarding the recommendation of projects, budgetary allocations to countries, appointment of staff by nationality, and other matters. Continuity of the elected leadership, however, has been the norm. Although the first Director-General, Dr Brock Chisholm, served for only 5 years (1948-1953), his successor, Dr Marcolino Candau, served for 20 years (1953-1973), and Dr Halfdan Mahler has held the office since that time. For most regional directors, a long term of office has likewise been the norm.

### The Members and Governing Bodies of WHO

The World Health Assembly, which decides WHO's policies and programmes, consists of delegates representing Member States, each Member State having one vote. It normally meets once a year, usually in May. Guidance to the Health Assembly is provided by the Executive Board, a smaller body, whose members serve in a personal rather than an official capacity but are designated by the governments of Member States elected by the Health Assembly. The Board meets twice a year, the main meeting being held in January, while a second, shorter, meeting takes place immediately after the Health Assembly.

The Twelfth World Health Assembly (1959) and the Nineteenth World Health Assembly (1966) committed WHO to the global eradication of smallpox although some countries were not then Members of the Organization and hence not party to these decisions. Among those which, in 1966, were not yet Members or were not yet directly represented were the People's Republic of China, the German Democratic Republic, the Democratic People's Republic of Korea and the Socialist Republic of Viet Nam. Until the 1970s, no official communication between

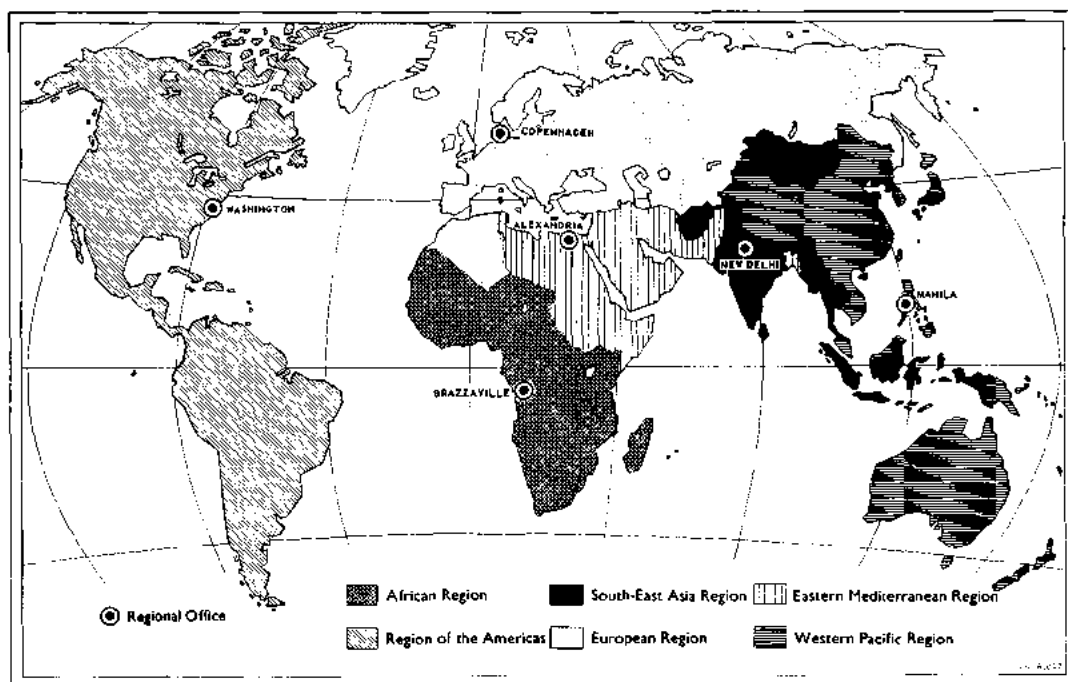

Fig. 10.1. WHO regional offices and the areas they served, December 1967. Whereas there were 167 Member States and Associate Members of WHO in December 1986, there were only 129 when this map was prepared (from World Health Organization, 1968a). A number of countries or territories shown here as served by WHO regional offices were not directly represented in WHO in 1967, the largest among them being the People's Republic of China

WHO and these governments was possible and little official information was available from some of them about the status of smallpox in their countries. None was thought to have endemic smallpox in 1966, although it was not possible to confirm this until after they became Member States of the Organization. Besides these countries, there were 4 other large territories, all in Africa, which in 1966 either no longer participated in WHO (South Africa) or were represented by colonial powers (Angola, Mozambique, and Southern Rhodesia). All except Angola had endemic smallpox in 1967. Until the 1970s, however, it was difficult or impossible for WHO to communicate with these countries as well, either about the occurrence of smallpox or about the status of their programmes. Thus, effective universal participation in the smallpox eradication programme was not achieved until a number of years after the Intensified Programme had begun, and not until 1979 were communications adequate with all countries so that global eradication could be certified.

Each Member State is attached to one of WHO's 6 regions (Fig. 10.1), only 4 of which had endemic smallpox in 1967—Africa, the Americas, South-East Asia and the Eastern Mediterranean. Regional committees, at which Member States of the respective regions are represented, meet once a year to decide regional policy and to examine the regional director's proposed programme budget for transmission to the Director-General and inclusion in the Organization's global programme budget.

The type of representatives sent by Member States to the Health Assembly and the regional committees had a bearing on the smallpox eradication programme and on the outcome of resolutions. An analysis of delegates to the Twentieth World Health Assembly (1967) showed that 80% were representatives of health ministries (Jacobson, 1973); while that was logical and often advantageous, it was sometimes a handicap to obtaining voluntary contributions from governments and to securing national commitment to undertake eradication programmes. Volun-

tary contributions from the industrialized countries were usually provided by a development agency separate from the ministry of health and, as experience showed, liaison between the two was frequently deficient. Programme policies and needs identified by the World Health Assembly were often not understood by the development agencies and sometimes, because of this, appeals for voluntary contributions went unheeded. The way that the countries with endemic smallpox were represented also gave rise to problems. Ministries of health, to which most delegates belonged, were often politically weak, the minister often not being of cabinet rank. Decisions with regard to the allocation of national resources were often made elsewhere in government—e.g., in planning departments, few of whose members attended the World Health Assembly. Thus, the commitment of some Health Assembly delegates to undertake national programmes meant little from the point of view of their implementation.

### Role of the Director-General

Decisions on policy and budgetary allocations were ultimately the responsibility of the Health Assembly, acting on the advice of the Executive Board but, as Jacobson (1973) points out:

"The Director-General initiates the process of formulating WHO's budget and establishes guidelines ... Later he compiles the proposals of the headquarters staff and the regional offices. At both stages he has opportunities to make important judgments about allocations among functions and regions. The formal position of the Director-General makes him an initiator, controller and vetoer as far as programmatic decisions are concerned."

The minutely detailed budgets proposed by the Director-General were seldom altered either by the Board or by the Health Assembly; moreover, after they had been approved, he had considerable discretionary authority to transfer funds from one programme to another and from country to country as need and opportunity dictated.

Changes in WHO policies were less likely to be impeded by long-established career staff than in many other large administrations. Relatively few had career service appointments in comparison with some other international organizations. From the time of

WHO's foundation, a continuing turnover of personnel had been considered helpful in sustaining a high level of professional expertise. Thus, in 1969, only 20% of professional staff at Headquarters and the regional offices and about 5% of those working in field projects had career service appointments (Jacobson, 1973). In the same year, only 29% of the staff had served in WHO for more than 5 years.

For these reasons, WHO's limited financial support for smallpox eradication prior to 1967 (see Chapter 9) reflected the concerns and priorities of the Director-General at least as much as those of the Health Assembly. His attitude in turn reflected, in large measure, his scepticism as to the possibility of achieving global smallpox eradication until basic health services in all countries had been greatly strengthened, a scepticism shared by many scientists and health officials at that time. His doubts had been reinforced by the recommendation of the WHO Expert Committee on Smallpox (1964), discussed in the preceding chapter, which implied that everyone would have to be vaccinated to ensure eradication. Since, for example, there were tribes in the Amazon basin with which national authorities had little or no contact, it was apparent that universal vaccination was not then possible. For the Organization to be committed to an unattainable objective when, at the same time, its only other global eradication programme—that for malaria—was in serious difficulty, could jeopardize WHO's technical credibility. Moreover, the Director-General foresaw the possibility of another single-purpose eradication programme diverting national and international resources and attention from the important, but difficult and less glamorous, task of developing basic health services. He frequently pointed out that, if additional funds were to be allocated to smallpox control, they should be provided in the form of voluntary contributions by the industrialized countries, which would benefit by having fewer imported cases of the disease to deal with.

The decision, in 1966, by the Nineteenth World Health Assembly to establish a special allocation for smallpox eradication in the Organization's regular budget required WHO to undertake a more vigorous programme, but the additional funds did not allay the Director-General's concerns about the Intensified Programme's prospects of success.

**Plate 10.1.** Halfdan T. Mahler (b. 1923) took office as Director-General of WHO in July 1973. His long career in international public health had included almost 10 years as a senior WHO officer with the Indian national tuberculosis programme. This involved the application of methods of operations research that proved valuable when, as Chief of the WHO Tuberculosis unit, 1962-1969, he worked with the Smallpox Eradication unit to overcome the problems of the simultaneous administration of BCG and smallpox vaccines. He had been an Assistant Director-General of WHO from 1970.

### WHO Programme Management in Geneva

The management and supervision of technical programmes at WHO Headquarters differed from what an organizational chart (Fig. 10.2) might suggest, as is indeed the case with many organizations. During Dr Candau's term of office as Director-General, technical programmes at WHO Headquarters were usually monitored by the Director-General and the Deputy Director-General, Dr Pierre Dorolle, through direct contact with the chiefs of the respective technical units. The senior intermediate positions in this inter-governmental organization—assistant directors-general and directors of divisions—had many representational duties and were often relatively little concerned with the day-to-day activities of the technical units. Over the 20-year period during which Dr Candau was Director-General, the Organization grew in size and the number of activities and technical units multiplied,

making direct supervision of each of them increasingly difficult. Smallpox eradication programme staff seldom met the Director-General until Dr Halfdan Mahler assumed the post in 1973. Contacts with the responsible assistant director-general were likewise uncommon before Ladnyi's appointment to this position in 1976. Among those who served as directors of the Division of Communicable Diseases, Dr Karel Raška, who held this post until early 1970, took a particular interest in smallpox eradication and actively supported the programme.

The Smallpox Eradication unit had, of necessity, a closer, continuing relationship with those responsible for WHO's administration and finance. Until 1971, the Assistant Director-General responsible for this area, Mr Milton P. Siegel, an active proponent of smallpox eradication, directed these activities and those reporting to him took a similar interest in the programme. Both during and after his period of tenure, most of them went out of their way to provide help and guidance.

Throughout much of the smallpox eradication programme, the unit, as far as the management of its technical activities was concerned, functioned relatively autonomously. This meant that it could alter smallpox programme policies and make other decisions quickly, but it made it more

Carney (b. 1920), Chief, Finance and Accounts, 1972-1980.

difficult to implement the necessary changes and to persuade regional directors, government officials and donor agencies of the programme's need for support.

### The Smallpox Eradication Unit in Geneva

The Smallpox Eradication unit in Geneva consisted throughout most of the programme of only 10 persons—4 medical officers, 1 administrative officer, 1 technical officer and 4 secretaries. Even this number had originally been considered excessive by senior WHO staff, who then envisaged the unit's activities as consisting of little more than ensuring that each country received adequate resources for conducting mass vaccination campaigns (see Chapter 9). During the first year of the Intensified Programme, however, it became apparent that far more than this was required and, indeed, that additional personnel would be useful. However, requests for additional staff were rejected, in part because of pressures by WHO Member States to limit the size of Headquarters staff. But short-term consultants could be recruited, and in 1968-1969, Dr Gordon Meiklejohn served on the staff during a sabbatical year's leave from the University of Colorado; in 1969-1970, Dr

Paul Wehrle, on similar leave from the University of Southern California, also worked in the unit. Every year subsequently, each undertook special tasks on behalf of WHO for 4-6 weeks during his university vacation.

Some compensation for the dearth of staff was provided by the fact that many of those in the Headquarters Smallpox Eradication unit served for long periods; this ensured continuity and consequently a greater ability to anticipate the problems of the Organization and of governments in the endemic countries (see Table 10.1).

Late in 1970, an interregional team of 3 additional medical officers was authorized to provide short-term emergency assistance wherever required and to help in establishing surveillance programmes where these were lacking. One was recruited and assigned to Ethiopia, in which that greatly understaffed programme was just beginning, and 2 to West Pakistan when that region was divided into 4 provinces with 4 essentially autonomous smallpox programmes (see Chapter 14). As their presence in these assignments continued to be necessary, they were effectively lost to the Headquarters complement, though remaining chargeable to the Headquarters budget since the Regional Office for the

Dr Isao Arita	Medical Officer	1965-1977	WHO adviser in Liberia, 1963-1965
	Chief Medical Officer	1977-1985	
Dr Zdeněk Ježek	Medical Officer	1980-1985	WHO Smallpox Eradication and Epidemiological Advisory Team, South-East Asia Region, 1972-1977; WHO adviser in Somalia, 1977-1979
	Chief Medical Officer	1985-1987	
Dr Ehsan Shafa	Medical Officer	1971-1977	WHO Regional Adviser on Smallpox Eradication, Eastern Mediterranean Region, 1967-1971
Dr Stephen Falkland	Medical Officer	1966-1969	
Dr Georgij Nikolaevskij	Medical Officer	1967-1971	
Dr Anatolij Slepushkin	Medical Officer	1971-1976	
Dr Joel Breman	Medical Officer	1977-1980	AID adviser in Guinea, 1968-1970
Dr Alexander Gromyko	Medical Officer	1977-1983	WHO short-term consultant in India, 1974
Dr Lev Khodakevich	Medical Officer	1983-1986	WHO adviser in India, 1973-1977, and in Ethiopia, 1978-1979
Mr John Copland	Administrative Officer	1966-1977	
Miss Ija Jurjevskis	Technical Officer	1967-1969	
Mrs Linda Licker	Technical Officer	1969-1970	
Mr John Wickert	Technical Officer	1970-1977	
	Administrative Officer	1977-1979	
	Consultant	1983-1987	
Mr Robert Evans	Technical Officer	1978-1979	AID adviser in Nigeria, 1968-1970
	Administrative Officer	1980	
Mr James Magee	Public Information Officer	1978-1980	

Eastern Mediterranean stated that it had no funds with which to take them over. Other efforts to increase the size of the Headquarters Smallpox Eradication unit were unsuccessful. In consequence, the few professional staff based in Geneva of necessity undertook a wide range of activities both at Headquarters and in the field. As the programme progressed, they had to travel more and more, to the point that most were in travel status for 50–70% of the time.

A partial listing of the activities undertaken by the unit gives some insight into the nature of day-to-day operations. In the interests of the morale of field staff and the acceleration of operations, priority was given to all communications from the field, the aim being to respond to queries or requests within 48 hours of receipt. A surveillance report was prepared for publication every 2–3 weeks in the *Weekly epidemiological record* and more extensive summary reports on the programme twice a year. Voluntary contributions were repeatedly sought through special mailings and visits to governments and other potential donors. Arrangements were made for the testing of vaccine and for its shipment to a central depot in Geneva. Stocks of

vaccine, bifurcated needles, jet injectors, kits for the collection and dispatch of specimens and training aids were kept in Geneva and sent on request, to countries. Specimens from patients were received weekly from different countries, repacked and sent to reference laboratories for testing; the results were sent by telex to those submitting the specimens (see box). Each year 1–2 international meetings were arranged for senior smallpox eradication programme staff from regional groups of endemic countries, as well as annual conferences of WHO's regional smallpox advisers, biennial meetings of the research group concerned with monkeypox and related problems, meetings of the WHO Expert Committee and the WHO Scientific Group on Smallpox Eradication, and a special meeting dealing with vaccine production. Various training and educational instruments were prepared—manuals, posters, slide series, teaching exercises and films. An extensive correspondence was conducted on the recruitment of personnel, regional and national budgets and programmes, and the procurement of supplies and equipment. Press releases were prepared and media queries answered. Reports from field staff dealing with their work and observations were edited and published twice a month.

Because of the heavy travel commitments of the unit's staff, there was insufficient time to perform all these functions well. Had there been adequate manpower, the following 3 activities, in particular, could usefully have received more attention and this, almost certainly, would have reduced the time required to achieve eradication: (1) field studies to define more precisely the status and epidemiology of smallpox in different areas and to evaluate alternative methods of smallpox control; (2) field demonstrations, extending over 2–3 months, of surveillance-containment methods; and (3) personal contacts with potential donors to explain the programme and to seek support.

The Smallpox Eradication unit had comparatively few collaborative relationships with other technical units at WHO. One other unit with which it worked closely was that responsible for implementing the provisions of the International Health Regulations. This unit received weekly telegraphic reports of cases of the quarantinable diseases, including smallpox, and published them in the *Weekly epidemiological record*. These activities are described below, in the section

**Plate 10.4.** Participants in the meeting of the WHO Expert Committee on Smallpox Eradication in November 1971. The chairman (right) was Francis C. Grant (b. 1924) of the Ministry of Health of Ghana, who had been a smallpox eradication consultant for WHO in Burma in 1970. The rapporteur was Paul F. Wehrle (b. 1921), a United States professor of paediatrics who had helped to establish the global eradication programme while serving as a WHO consultant in Geneva, 1969–1970.

**Plate 10.5.** Staff of the Smallpox Eradication unit at WHO Headquarters. **A:** Donald Ainslie Henderson (b. 1928), Chief, 1966–1977. **B:** Isao Arita (b. 1926), Medical Officer, 1965–1976; then Chief, 1977–1985. **C:** John S. Copland (b. 1930), Administrative Officer, 1967–1977. **D:** John F. Wickett (b. 1944), Technical Officer, then Administrative Officer, 1970–1980, and consultant, 1983–1987. **E:** Susan E. Woolnough (b. 1948), secretary to Henderson and Arita, 1970–1985. **F:** Celia I. Sands (b. 1945), secretary, 1969–1981.

**Plate 10.6.** Kit provided by WHO for the collection and dispatch of virological specimens.

entitled "Surveillance and notification of smallpox cases". Collaboration with such units as those dealing with health education and maternal and child health would have been logical and potentially productive but most of them were small, with only 2 or 3 professional staff, few of whom were directly concerned with field operations. The only programme of substantial size and with extensive field activities was that for malaria eradication, but by the mid-1960s it had begun to encounter major problems which fully occupied its staff. The only other immunization programme, until 1975, was that for tuberculosis, which was the responsibility of the Tuberculosis unit. However, the staff of that unit were also few in number and much of their time was devoted to field trials aimed at assessing the efficacy of BCG vaccination.

### WHO Regional Offices

The WHO regional offices were positioned administratively between WHO Headquarters and countries and were expected to play a major role in the development and coordination of all types of country programmes in their respective regions. For them, the Intensified Smallpox Eradication Programme differed from others for which they were responsible in that it required more or

less simultaneous activities in all countries, both to monitor the occurrence of smallpox and to undertake programmes to eradicate the disease or to detect and contain importations. Its needs were different, therefore, from those of tuberculosis control or maternal and child health, for example. Programmes such as these were often country-specific, and it was usually of little moment to the region as a whole or to other countries whether one or more countries did or did not undertake special activities or whether a given disease was widely prevalent elsewhere or not. It might seem that experience acquired in malaria eradication would provide a model, but it did not. National malaria eradication programmes had been implemented with WHO assistance in South America and Asia but in only one country of sub-Saharan Africa (Ethiopia). Most of the smallpox-affected countries that also had endemic malaria had not progressed beyond the "attack phase", in which systematic spraying was the primary activity. Even where there was surveillance it tended to be purely national in character, since knowledge of the malaria status of neighbouring countries was of little interest except in certain border areas.

Most WHO regional offices did not, at that time, initiate health programmes. Rather, they responded to requests for assistance from governments. Owing to budgetary constraints, the travel of regional office staff

### Processing of Specimens from Suspected Smallpox Patients

Specimens from suspected smallpox patients from all parts of the world were sent to Geneva and, once a week, sent by air, alternately to the WHO collaborating centres in Atlanta (Center for Disease Control) and Moscow (Moscow Research Institute for Viral Preparations). This practice was followed so as not to overburden either laboratory. Most specimens were received in Geneva in collection kits designed and provided by WHO (see Plate 10.6). The kit included a stylette and swabs for taking specimens, and a screw-capped glass vial into which the specimen was to be placed and which, in turn, fitted into a screw-capped metal container. Two copies of a form providing identifying information about the patient were wrapped around this second container and the contents placed in yet a third screw-capped cardboard shipping container. When received in Geneva, only the outer container was opened, one copy of the form removed and the specimen logged in. Laboratory results were sent to Geneva from the laboratory by telex or telephone and relayed, in turn, to the responsible health administration.

Although no problems arose with this method of handling specimens in Geneva, it is seen, in retrospect, to have been less than satisfactory, since it assumed that neither the form nor the second container was contaminated with variola virus and thus capable of causing infection. However, health officials in some countries sent specimens in other types of containers, including envelopes and small boxes, which were sometimes only partially sealed. Miss Sands, who dealt with the specimens, was revaccinated every year, as were all the staff, but she opened and processed the specimens at an ordinary secretary's desk in an open room.

While unthinkable now, the system, at the time, appeared to provide reasonable safeguards against the chance infection of others in Geneva. The infection of personnel handling specimens, even in laboratories, was uncommon and, until the mid-1970s, laboratory precautions consisted in little more than the vaccination of personnel. The occurrence of smallpox in 1978 in Birmingham, England, in a person exposed to virus carried by an air duct from one room in a laboratory to another demonstrated the need for more stringent precautions.

Another concern present throughout the course of the programme was that of the possible loss of specimens in shipment. Thanks to a rigorous, continuing check of bills of lading against receipt of shipments, this did not occur, but, as a precaution, specimens sent from Geneva to Moscow and Atlanta were packed in large containers which would be less likely to be mislaid.

tended to be restricted. Efforts to persuade WHO regional directors that the needs of global smallpox eradication called for a somewhat different approach met with only limited success, varying from region to region. The Region of the Americas and the Eastern Mediterranean Region immediately appointed full-time advisers on smallpox eradication, and a year afterwards two medical officers in the South-East Asia Region were given full-time responsibility for smallpox eradication. In these regions, programme planning, the recruitment of staff and the procurement of supplies and equipment were most efficiently conducted. In the African Region, however, until certification activities began, responsibilities for the smallpox eradication programme were assigned as

a part-time responsibility to the adviser on tuberculosis or on all communicable diseases. Not only did this region include more countries than any other, with some of the world's least developed health systems but, in addition, communications between the regional office and countries were poor and travel was difficult. As is described in the chapters dealing with field operations, there were continuing problems of every type in endeavouring to develop and support national programmes. In all regions, however, a lack of personnel in the regional offices and the customary constraints on their travel handicapped programme development. Where only a single adviser was involved, his absence on leave or duty travel meant that communications often went unheeded and

other activities, such as recruitment and the procurement of supplies and equipment, slowed down or ceased altogether. As a result, Headquarters staff travelled far more frequently and extensively than might otherwise have been necessary for a programme having a regional structure.

The regional offices were at that time likewise largely unaccustomed to the coordination of plans, needs and resources within a global context. To try to achieve better coordination, the Headquarters Smallpox Eradication unit held annual meetings for those responsible for smallpox eradication in each region to discuss goals, plans and progress. At the meetings, priorities were decided and needs identified, including funds, vaccine, vaccination instruments, personnel, and training aids. Such meetings were usually held in conjunction with a WHO-organized multinational meeting of programme staff, at which strategy and recent field observations were also discussed. Whatever the venue, it was always necessary to make a special appeal to one or several of the regional directors to obtain permission for advisers to attend, a permission which was

usually but not always granted and then only on the condition that Headquarters funds would be used for travel. Although the meetings proved invaluable, it was never possible to achieve a rational allocation of funds, as will be discussed later.

### WHO Representatives in Countries

The WHO representatives in countries provided the point of contact between WHO and the countries; they were assigned to most developing countries to assist in formulating policy and developing projects, and to provide administrative and technical guidance to WHO-supported programmes. Some of them had had many years of experience in international health work, but most were recent recruits who had held senior positions in their own national health services. They took up their positions after a short briefing, largely of an administrative character, and usually met their regional directors and other WHO representatives once or twice a year. Few were experienced or knowledgeable in smallpox eradication and, because of their

**Plate 10.7.** **A:** Nicole Christiane Grasset (b. 1927) served as adviser for smallpox eradication in the South-East Asia Region of WHO, 1970–1976, succeeding Jacobus Keja who had been an adviser there from 1967. **B:** Ahmad J. Hajian (b. 1920) was the smallpox eradication adviser in the Eastern Mediterranean Region of WHO, 1971–1977, replacing Ehsan Shafa (Plate 10.12).

numerous other responsibilities, few could make any substantial contribution specifically to the Intensified Programme.

### Smallpox Eradication Programme Staff

The quality and commitment of international staff proved to be one of the most important factors in the successful eradication of smallpox, and considerable time and effort were expended by the Smallpox Eradication unit on recruiting them. The task was not an easy one, however. Epidemiologists with experience in infectious disease control were particularly desirable because of the need to initiate and foster epidemiological surveillance. In 1967, however, few were available, and of those who were, almost none had ever seen cases of smallpox. Most were recruited on the strength of their experience in the management of health programmes, special consideration being given to basic competence and motivation. Specialized training in smallpox eradication methods would have equipped them better for their assignments but many difficulties were encountered in providing it. Thus, adequate numbers of fully qualified staff did not become available until the Intensified Programme was well advanced.

The provision of special training programmes in smallpox eradication proved impracticable, except for international and senior national staff working in the programme conducted with United States assistance in western and central Africa. For these, from 1966 onwards, the Communicable Disease Center (which has been renamed on several occasions and is now the Centers for Disease Control and widely known simply as CDC) provided a 4-week training course every year. Only a few WHO staff attended because WHO regional offices were unaccustomed to providing specialized training for newly recruited staff, as most were already experienced in the work that they were expected to do. In any event, by 1970, because of the early interruption of smallpox transmission in western and central Africa (see Chapter 17), the CDC course had so changed in character as to be of limited value for those engaged in the early phases of an eradication programme. WHO had provided specialized training at malaria eradication centres, but smallpox eradication was widely perceived as consisting in little more than mass vaccina-

tion, for which little specialized knowledge was thought to be needed. A WHO-conducted interregional training course was not available as an option because most regional offices did not wish to incur the expense of sending new advisers to Geneva for briefing. Most new staff therefore took up their positions with a briefing of a week or less in their respective regional offices, provided that there was a smallpox adviser in the region to brief them and that he was not then on duty travel. Not until 1974, when the number of international staff increased substantially, did WHO begin to provide organized training programmes for its staff. These were conducted at national level, first in India and then in Bangladesh and Somalia, concurrently with their large-scale intensified programmes.

Other methods were used to educate and orientate newly recruited staff. It was believed and subsequently confirmed that the clinical characteristics of smallpox could soon be learned after arrival in the country. For this purpose, the following were available: the WHO Handbook; a 4-colour, 8-page printed folder showing pictures of smallpox in African patients and describing the course of the disease (1969); sets of teaching slides showing smallpox in African patients (1969) and Asian patients (1971); and a large wall chart showing the appearance of smallpox and chickenpox rashes at various days after the onset of the disease (1970).

The epidemiological principles underlying proper surveillance and containment proved more difficult to convey. Many different approaches were used, beginning with the instructions provided in the WHO Handbook. Later, two case histories with syllabuses were developed, one dealing with techniques for the investigation and control of an outbreak (SE/71.1) and the other with surveillance-containment measures to be taken in an area with a population of about 2-3 million (SE/72.7). (The latter was adapted for use as a case history by the Harvard School of Business Administration.) On-site tutorial training was provided by WHO Headquarters and some regional smallpox eradication programme staff, and periodic intercountry meetings were structured to emphasize surveillance-containment methods and to illustrate approaches. Reports and materials distributed every 2-3 weeks in the so-called "biweekly mailing" (see below) also proved useful. All these efforts, however, fell short of what was required, as was shown by

the length of time required to implement surveillance-containment programmes in most areas and the fact that some African countries were never fully successful in doing so.

Difficulties in communicating with staff working in the field also hampered efforts to develop expertise and solve problems. All communications from Headquarters had to be routed through the appropriate regional office, logically the principal point of contact for the countries in that region. Where there was a full-time smallpox adviser and the region comprised few countries—South-East Asia, for example—reasonably close contact with field staff and programmes in the countries was possible. Where there was no full-time adviser and the countries in the region were numerous, as in Africa, communications were difficult and special measures were necessary. The nature of the problems may be illustrated by the fact that, if a letter was sent from Geneva to the regional office inquiring about the status and needs of a national programme, it was usually necessary for a regional adviser to prepare a special letter for the signature of one of his superiors or the regional director. After drafting and revision, the letter would then be sent to the WHO representative, who would contact either the WHO smallpox adviser or the national health authority. When the information had been obtained, a letter of reply would be prepared and the procedure repeated in reverse. Since the mail was slow and unreliable almost everywhere, it was exceptional to receive a reply to a query from Geneva in less than several months, if it was received at all.

This problem was overcome to some extent by arranging for copies of important correspondence and telex messages to be sent direct from a country to Geneva, and for Headquarters staff, likewise, to send a copy of the reply to the country, the original being sent to the regional office as prescribed. This was of crucial importance in many instances, for example, in dealing within days with an acute shortage of vaccine in Uganda at a time when a telex message "through the proper channels" took 8-9 weeks. Although this approach violated the prescribed procedures, field staff frequently noted that the immediate responsiveness of Headquarters staff to their requests and queries played an important role in sustaining morale and giving impetus to the programme.

Up to the end of 1967, WHO smallpox eradication programme staff throughout the world numbered less than 30. Additional WHO staff were required as national programmes began but recruitment proceeded slowly, the ability and dedication of recruits varying greatly. Except for those who were assigned to Geneva or were members of an interregional team, recruitment and selection were the responsibility of the regional offices, whose personnel services operated independently of Headquarters. Headquarters smallpox eradication staff endeavoured to assist the regional offices in identifying suitable candidates through personal contacts and the screening of applications received in Geneva, but proposals at first were as often ignored as accepted. An especially discouraging episode was the assignment by one regional office of a particularly well qualified candidate to an entirely different programme after months of work by Headquarters smallpox eradication staff to recruit him to WHO for work on smallpox eradication.

Because of the problems, such impetus as the programme possessed during its first few years was provided by a very small number of qualified WHO staff, the staff of the programme conducted with United States assistance in western and central Africa, and national staff. Among the WHO staff were Dr Pierre Ziegler, who worked in Zaire; Dr Celal Algan in Rwanda; Dr Karel Markvart in East Pakistan; Mr Henry Smith in Kenya; Mr Leo Morris in Brazil; Dr Jacobus Keja in the Regional Office for South-East Asia; and Dr Ehsan Shafa in the Regional Office for the Eastern Mediterranean. Eventually, however, a reasonably satisfactory collaborative relationship with respect to recruitment evolved between Headquarters and two of the four Regions concerned.

At first, many international staff were transferred from other projects which were not progressing well or in which the staff had proved unsuitable. Over a number of years, some of the less effective and less industrious staff were transferred by WHO to yet other programmes or did not have their contracts extended. A stated policy of the programme that all smallpox eradication staff should spend at least one-third of their time in the field facilitated this weeding-out process, the policy being monitored, where necessary, by review of daily tour diaries.

Especially helpful in the recruitment of more capable staff were senior epidemiolo-

Stages  
of rash

**Plate 10.9.** The left-hand portion of a large wall poster that contrasted the rashes of smallpox and of chickenpox on 4 areas of the body. English, French and Portuguese versions of this poster were prepared in 1970.

# CHICKENPOX

Stages  
of rash

If smallpox is suspected notify the health authority immediately. Isolate the patient and vaccinate all contacts.

## smallpox

- The smallpox patient becomes ill between 7 and 17 days after close contact with someone who has the disease
- The patient has fever and does not feel well for 2 to 4 days before a rash appears
- The poxles are most numerous on the face, arms and legs
- Poxles are usually present on the palms and soles
- Scabs begin to form 10 to 14 days after the rash appears
- Scabs fall off 14 to 28 days after the rash begins

smallpox - distribution of the rash

## chickenpox

- The chickenpox patient becomes ill between 14 and 21 days after close contact with someone who has the disease
- The patient usually has no symptoms until the rash appears
- The poxles are most numerous on the body
- Poxles are seldom present on the palms and soles
- Scabs begin to form 4 to 7 days after the rash appears
- Scabs fall off within 14 days after the rash begins

chickenpox - distribution of the rash

**Plate 10.10.** The right-hand portion of the poster in Plate 10.9. The text and drawings at the bottom gave simple indications by which to distinguish the signs and symptoms of smallpox from those of chickenpox.

**Plate 10.11.** The front and back of two versions of the shirt-pocket-size WHO smallpox recognition card produced in 1972. They were first used in India, and tens of thousands were eventually distributed to search workers throughout the subcontinent. The first version (upper pictures) was selected to portray a patient with relatively mild smallpox; it is a reduced version of the larger card shown in Plates 10.29 and 10.30.

**Plate 10.12.** **A:** Zdeněk Ježek (b. 1932) was attached to the WHO Regional Office for South-East Asia in 1972, working for smallpox eradication in India. He later served in Somalia, before joining the Smallpox Eradication unit at WHO Headquarters in 1980 and succeeding Arita as Chief of the unit in 1985. **B:** Ehsan Shafa (b. 1927) was the smallpox eradication adviser in the Eastern Mediterranean Region of WHO, 1967-1971, and then served with the Smallpox Eradication unit at WHO Headquarters until 1977.

gists from a number of countries who were interested in the programme and aware of its demands and who screened and referred former students and colleagues. Such epidemiologists included Dr Karel Raška, Czechoslovakia; Dr Jan Kostrzewski, Poland; Dr Holger Lundbeck, Sweden; Dr Viktor Zhdanov, USSR; and Dr Paul Wehrle, USA. From early in 1972, when smallpox epidemics unexpectedly occurred in Bangladesh, until 1977, Dr David Sencer, then Director of CDC, made available the services of 5 full-time CDC staff, and from 1974, the High Institute of Public Health in Alexandria, Egypt, provided a number of faculty members and former students.

As the programme progressed, the number of capable staff with field experience gradually increased, and those who had successfully worked in their own national programmes were recruited for service in other countries. These included staff from Afghanistan, Bangladesh, Brazil, India, Indonesia, Nepal, Pakistan, the Sudan, Togo and Yemen.

International volunteers contributed significantly, both while serving as such and subsequently when recruited as consultants or staff. Arranging such volunteer support was difficult, however, because WHO policy until the mid-1970s was that volunteer assistance had to be arranged strictly between recipient and donor governments, WHO staff

not being allowed to assist in the process. Unofficial contacts and private correspondence, however, served to facilitate the assignment of United States Peace Corps volunteers in Afghanistan, Ethiopia and Zaire; volunteers from Japan and Austria, who served in Ethiopia; and British volunteers from OXFAM (a British private charitable organization), who worked in India and Bangladesh. Regrettably, an offer by Sweden, in 1970, to assign young medical officers at Swedish government expense to WHO itself had to be rejected by the Organization for policy reasons.

Until 1973, international staff assigned to a country rarely numbered more than 1-4, with the exception of large countries and those with an especially difficult terrain and a shortage of national personnel—Afghanistan, Bangladesh (from 1972), Ethiopia, Nigeria and Zaire. From 1973 onwards, increasingly large numbers of international staff worked in Bangladesh and India and later in Ethiopia and Somalia as more funds became available and efforts were intensified to achieve eradication in the shortest possible time. Throughout the course of the global programme, however, international staff of all types at any given time never numbered more than 150. In all, 687 WHO staff and consultants from 73 different countries eventually served in the programme for periods

ranging from 3 months to more than 10 years; approximately 125 others served with the programme under bilateral agreements. Most of the staff were less than 40 years of age and some less than 30, youth being an advantage where living and travelling conditions were difficult.

Although international staff were few, they played an important role in sustaining national government support, providing programme continuity where national leadership changed for political or other reasons, and expediting the transfer of new techniques from one programme to another. In retrospect, it may be said that few national programmes achieved much success where international staff were of poor quality, but national staff, given the necessary support and encouragement, showed themselves to possess a skill and dedication which equalled and often exceeded those of the international advisers.

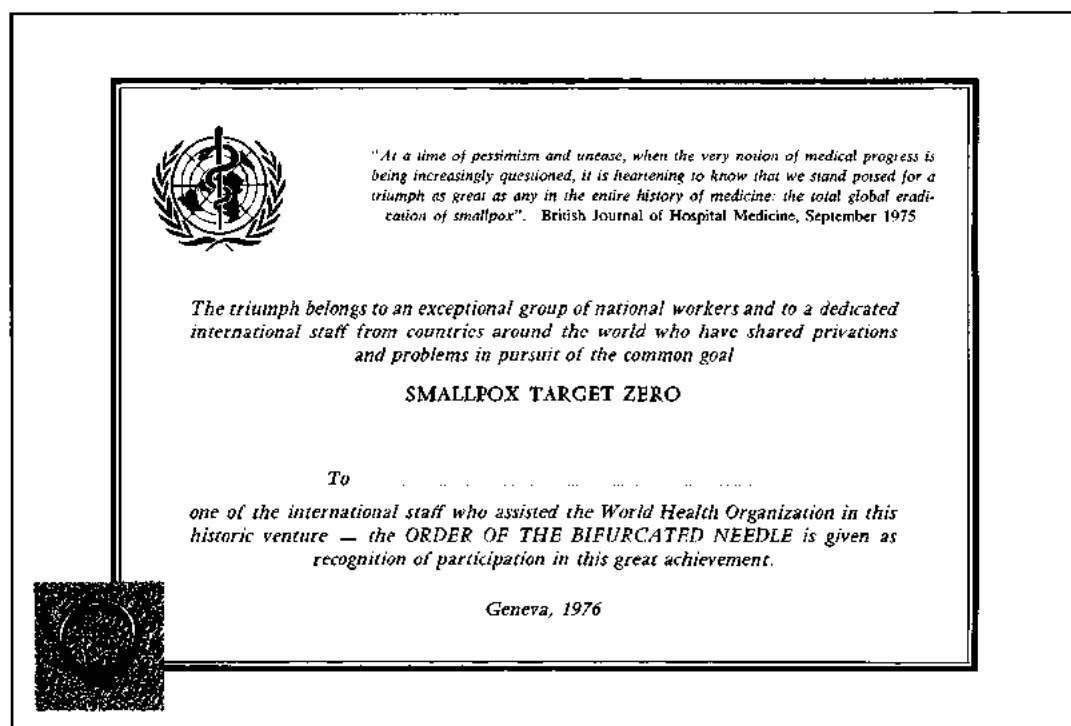

### **OBTAINING NATIONAL AGREEMENTS TO UNDERTAKE PROGRAMMES**

Although commitments assumed by governments by virtue of votes in favour of resolutions at the World Health Assembly were morally binding, WHO could not force governments to undertake programmes. Thus, although the Intensified Smallpox Eradication Programme was unanimously approved by the Health Assembly, only certain countries were, in fact, then prepared to undertake eradication programmes—much as had been the case during the period 1959–1966. Some lacked resources, while others considered that other health problems were of higher priority. Universal participation was essential if the programme was to succeed but, as described earlier, WHO's role in actively promoting and advocating a particular programme in all countries was an unaccustomed one. Malaria eradication was the only other programme in which this had been attempted but, in that programme, the necessary but substantial additional national costs had distorted health allocations, and the extent to which its secondary objective, the improvement of basic health services, had been attained had fallen far short of expectations. Mindful of this experience and doubtful of the feasibility of smallpox eradication,

the Director-General cautioned his regional directors, at a meeting immediately after the 1966 World Health Assembly, against appearing to impose a smallpox eradication programme on any country. Thus, in 2 regions, Africa and South-East Asia (unfortunately also those most seriously affected by smallpox), the regional directors did not initially promote smallpox eradication programmes, assistance being provided only to countries specifically requesting it. In the Region of the Americas and the Eastern Mediterranean Region, however, eradication programmes were actively promoted from the beginning.

In the Americas, smallpox eradication was not a new objective, a regional eradication programme having been in existence since 1950 (see Chapter 9). A Regional Adviser on Smallpox Eradication, Dr Bichat Rodrigues, was appointed in 1966 to coordinate the effort, and Brazil, the only endemic country, committed itself to a national smallpox eradication programme employing what were then the new jet injectors (see Chapter 12). Vaccination campaigns in many other countries in South America began soon thereafter. In the Eastern Mediterranean Region, there were then 3 endemic countries—Ethiopia, Pakistan and Yemen—and there, also, an adviser on smallpox eradication, Dr Shafa, was immediately appointed. He successfully promoted programmes in Pakistan, Yemen and other countries of the region although, for reasons beyond his control, he was unsuccessful in Ethiopia, in which a programme did not begin until 1971 (see Chapter 21).

In the South-East Asia Region, the Regional Director shared the Director-General's belief that eradication represented an unattainable goal, given the stage of development of national health services (see Chapter 9). Responsibility for smallpox eradication was assigned to a 2-man intercountry advisory team which dealt with other communicable diseases as well and whose budget for travel was small. Little was done in the Region until Dr Herat Gunaratne was elected Regional Director in 1968; coming from Sri Lanka, a country which had eliminated endemic smallpox decades before, he saw no reason why this could not be achieved elsewhere. He therefore made the intercountry team, Dr Keja and Dr Louis Grem-liza, responsible solely for smallpox eradication and, from the time of his election, played

**Plate 10.13.** The contribution of the international staff who participated in the eradication of smallpox was given sincere if informal recognition by their promotion to the mock "Order of the Bifurcated Needle", accompanied by an official-looking certificate and a hand-made lapel pin. The pins (inset) were fashioned from bifurcated needles in the form of an "O" to symbolize "Target Zero", the objective of the programme.

an active role in encouraging national programmes. The response was generally enthusiastic and within a year effective programmes were in progress in all endemic countries of the region except India, where the programme started later (see Chapter 15).

In the African Region, by late 1966, a number of countries had already committed themselves to national smallpox eradication programmes. These included the 20 countries of western and central Africa which were participating in the smallpox eradication and measles control programme being carried out with the assistance of the USA; Zambia, which had begun a national vaccination campaign in 1966 because of epidemic smallpox; and Zaire, whose WHO-supported activities were then coordinated by Geneva Headquarters. The other African countries did not officially express any interest in 1966 and early in 1967. This was disturbing to the staff in Geneva, but also puzzling because funds were then available to meet all the costs of the programmes except salaries for the comparatively small number of national personnel who would be required. Because

WHO was prepared to provide vaccine free of charge and because many countries already employed smallpox vaccinators, it was actually cheaper for most of them to participate in the eradication programme than to continue smallpox control activities. They failed to express interest, as was later discovered, because no effort was made by the Regional Office to encourage programmes, acquaint national authorities with the programme's budgetary implications, or indicate the amount of support which could be provided by WHO; instead, the national authorities were expected to request WHO's assistance on their own initiative. The WHO representatives in the countries, as well as Ladnyi, then intercountry smallpox adviser for East Africa, were informed of this policy in September 1966. In the spring of 1967, the problem was resolved fortuitously when a member of the Headquarters Smallpox Eradication unit was given permission to visit several of the countries for the purpose of gathering information for the Director-General's report to the 1967 World Health Assembly. Although he was forbidden to

suggest to any country that a programme should be undertaken, he made the health authorities aware of the nature of the programme and the resources available and, within weeks, letters requesting WHO assistance were received from almost all of them.

By the summer of 1969, smallpox eradication programmes had begun in all the endemic countries in Africa except South Africa, Southern Rhodesia (now Zimbabwe) and Ethiopia. WHO then had no official relations with the first two of these, South Africa having ceased to participate in the Organization and Southern Rhodesia being technically still a colony of the United Kingdom, although it had unilaterally declared independence. Visits by WHO staff were not permitted and little information could be obtained about the status of smallpox or their programmes. However, neither was thought to represent a serious impediment to eventual global eradication because neither officially reported many smallpox cases and their health services were comparatively well developed. Both began special programmes in 1970 (see Chapter 20), stimulated largely by reports in the *Weekly epidemiological record*, which described excellent progress in smallpox eradication elsewhere in Africa but noted the lack of information from South Africa and Southern Rhodesia. The third country, Ethiopia, although in Africa, was served (until late in 1977) by the Regional Office for the Eastern Mediterranean and presented quite a different problem. Smallpox was widely endemic and health services were few, but malaria eradication staff and their international advisers, fearing that another programme would be a harmful distraction, persuaded government officials to refuse to discuss with WHO the implications of a smallpox eradication project. Not until late in 1969 did the government permit Henderson and Dr Shafa to visit the country. At that time, Ministry of Health officials declined to participate but the Emperor himself, who by chance had heard about the programme, intervened to commit the government and, in 1971, the last of the programmes in the endemic countries began (see Chapter 21).

Thus, although many countries needed to be encouraged and persuaded to undertake smallpox eradication programmes, these had, in fact, been initiated in all endemic countries within 5 years of the 1966 decision. It was quite another problem to ensure that the

various governments were sufficiently committed for eradication of the disease to be achieved.

### SUSTAINING GOVERNMENT INTEREST AND COMMITMENT

A continued high level of interest and support for the eradication programme was difficult to sustain in many countries, just as it was in WHO. Changes in governments and/or senior health personnel were often associated with differences in priorities and in levels of commitment. Smallpox was but one of many problems competing for attention and resources and, in countries in which the mild variola minor form was prevalent, it was understandably not of high priority. After the last known cases had occurred, resources were particularly difficult to obtain from recently endemic and donor countries, as well as from WHO itself, in order to continue surveillance and thus permit certification.

#### Role of the World Health Assembly

The World Health Assembly, convened each year for a period of several weeks, was a particularly important opportunity for promoting and sustaining interest in the smallpox eradication programme. Senior health officials from all Member States attended and, in addition to reviewing the proposed WHO budget, discussed the Organization's overall programme of work as well as specific programmes, such as that for smallpox eradication. During the debate, delegates frequently described what their own countries were doing, some asked questions of a technical nature and others took the opportunity to announce voluntary contributions. The Intensified Smallpox Eradication Programme, if included as an agenda item, might be discussed for 2-4 hours or more. Such a discussion served to focus the attention of health officials on the subject, and important principles—such as the role of surveillance and the need to use only freeze-dried vaccine—could be emphasized by the Secretariat. It also enabled government officials to hear what were often heartening or optimistic reports of progress in other countries, causing them to reexamine their own programmes. If, however, smallpox eradication was not included in the agenda as an item for

debate, it could still be discussed when the overall programme of the Organization was considered, but it was unusual for many delegates to prepare themselves to speak on the topic and the debate was usually brief.

Because the Health Assembly had identified smallpox eradication as a priority programme of the Organization and it had been on the agenda each year from 1959 to 1967, the Smallpox Eradication unit staff assumed that the topic would continue to be an annual subject for debate on which the Director-General would provide a special report to the Health Assembly. From 1968 onwards, however, it began to be omitted from the provisional agenda. The resolution on smallpox eradication adopted by the Twentieth World Health Assembly (1967), called only for the Director-General "to report further" on smallpox eradication to the Executive Board and the Health Assembly. "Further" was interpreted to mean at some time in the future and the topic was omitted from the provisional agenda of the Twenty-first World Health Assembly (1968), an action which was reversed at the request of the USSR. Resolutions adopted at the 1969, 1971, 1972, 1976 and 1977 Health Assemblies called specifically for special reports to each of the subsequent ones and for smallpox eradication to be included in their agendas. In the other years until 1977, when transmission was interrupted, smallpox eradication was the subject only

of a brief general discussion in the context of the overall WHO programme. A report by the Director-General was nevertheless prepared and kept in readiness in case one was requested by delegates. To it was attached a comprehensive review of the programme's progress and status that was published twice a year in the *Weekly epidemiological record* to coincide with the January session of the Executive Board and with the Health Assembly. Although the report was not to be distributed unless requested by delegates, the interest expressed, particularly by two delegates, one from the USSR and the other from the USA (Dr Dmitriy Venediktov and Dr Paul Ehrlich, Jr, respectively), ensured that it was distributed and the programme discussed.

### Surveillance Reports

Regularly published surveillance reports, both international and national, were an essential component of the surveillance process and, as experience had demonstrated in other disease control programmes, were also important in stimulating and sustaining the interest of those concerned with the programme. Such reports documented the numbers of cases reported weekly by administrative area, charted trends in incidence and in the progress of the programme, and discussed alternative strategies and tactics in

**Plate 10.14.** Two delegates to the World Health Assembly and members of the Executive Board of WHO who were strong advocates of smallpox eradication. **A:** S. Paul Ehrlich Jr (b. 1932), Surgeon General of the United States Public Health Service. **B:** Dmitriy D. Venediktov (b. 1929), Deputy Minister of Health of the USSR.

different areas. The first WHO surveillance reports on smallpox eradication were issued in September and December 1967, and from May 1968 onwards, they began to be published every 2-3 weeks in the *Weekly epidemiological record*, some 5000 copies being distributed to health officials and others throughout the world. The system was not established without difficulty, however, as is discussed later in this chapter in the section entitled "International surveillance reports". The WHO Regional Office for South-East Asia also issued surveillance reports from 1974 onwards, and national surveillance reports were published monthly and sometimes weekly or every 2 weeks in a number of countries.

In addition to providing information to widely scattered health staff, the reports also served to inform both public officials and the press, sometimes with unexpected consequences. When, in Brazil, Ethiopia and India, for example, better surveillance and improved reporting were accompanied by marked increases in the numbers of notified cases, national officials and the press expressed concern, and even alarm, although the increases were attributed, at least in part, to better reporting. Greater political commitment and increased resources soon followed. In other countries, interest in the programme grew significantly when national officials read of more satisfactory progress being made in other countries, some of which they believed to have health services inferior to their own.

### Interregional and Intercountry Meetings of Smallpox Eradication Staff

Meetings of senior staff from different national programmes also served to sustain and stimulate the interest of governments and staff while bringing to their notice the new observations which were being made. The WHO Headquarters budget provided for at least one such meeting a year, the venue changing from year to year, as did the participants (Table 10.2). In addition, over the period 1967-1972, CDC supported a yearly conference for the countries of western and central Africa.

The first of these meetings was held in Thailand in 1967 for countries in eastern Asia. At first they were largely devoted to the presentation of reports on national programmes by the respective national directors; over time, their nature gradually changed and each country was asked to present papers illustrating specific findings, the outcome of particular strategies and interesting new approaches. The ensuing discussions made it possible to determine whether the observations made in a particular national smallpox eradication programme were of relevance to the others. Most of these reports were distributed by WHO to all concerned with smallpox eradication through the special WHO/SE, SE and SME series of mimeographed documents (see References: WHO documents); some were also published in the medical literature.

Table 10.2. WHO seminars and meetings on smallpox eradication, 1967-1978 (excluding those associated with certification of eradication)

Date	Country in which held	Participants <sup>a</sup>
December 1967	Thailand	13 countries of South-East Asia, Eastern Mediterranean and Western Pacific Regions
November 1968	Zaire	11 countries of southern and eastern Africa
May 1969	Nigeria	18 countries of western and central Africa (joint seminar with CDC)
November 1969	Pakistan	11 countries of Eastern Mediterranean and South-East Asia Regions
December 1970	India	11 countries of South-East Asia, Eastern Mediterranean and African Regions
September 1972	Ethiopia	4 countries of eastern Africa
November 1972	India	5 countries of South-East Asia Region
November 1972	Pakistan	4 countries of Eastern Mediterranean Region
September 1973	Ethiopia	Ethiopia and WHO Eastern Mediterranean Region smallpox eradication advisers
November 1973	Pakistan	Pakistan and WHO Eastern Mediterranean Region smallpox eradication advisers
August 1974	India	Bangladesh, India and Nepal
January 1976	Nepal	6 countries of South-East Asia Region
March 1977	Kenya	4 countries of eastern Africa
September 1977	Kenya	5 countries of eastern Africa
April 1978	Kenya	5 countries of eastern Africa and the Eastern Mediterranean Region

<sup>a</sup> Participants included national programme staff and WHO smallpox advisers and other smallpox eradication staff from the regional offices and WHO Headquarters. Advisers from the regional offices in the 4 endemic regions were invited to all meetings from 1967 to 1970 and to the 1972 meeting in India.

**Plate 10.15.** Participants in the first interregional seminar on smallpox eradication held in Bangkok, Thailand, 11-16 December 1967. Left to right, front row: A. M. Khan (Pakistan), A. R. Rao (India), M. K. Singh (India), S. A. Mallick (Pakistan), D. A. Henderson (WHO), E. Na Bangxang (Thailand), S. Falkland (WHO), J. J. Dizon (Philippines), I. F. Setiady (Indonesia), U. Thaug (Burma); middle row: Z. Rahman (Pakistan), C. Rubinstein (WHO), C. H. James (United Kingdom), J. Singh (Malaysia), K. S. Ramakrishnan (India), G. P. Nikolaevskij (WHO), W. H. Foege (USA), J. Keja (WHO), B. Ignjatovic (WHO), F. G. L. Gremliza (WHO), B. Wirjodipoero (Indonesia), J. C. Pitkin (WHO), Khin Mu Aye (WHO), K. Chatyanonda (Thailand), S. Sornachai (Thailand); back row: C. Patanacharoen (Thailand), A. Prajapati (Nepal), J. S. Copland (WHO), T. M. Mack (USA), G. H. Waheed (Afghanistan), B. Chantasut (Thailand), E. Shafa (WHO), R. M. Lyonnet (WHO), Y. K. Subrahmanyam (India), S. Singh (WHO), P. Tuchinda (Thailand), T. Phetsiriseng (Lao People's Democratic Republic), N. D. Tiep (Viet Nam), P. Kunasol (Thailand), C. Debyasuvarn (Thailand).

The meetings had both tangible and intangible benefits. Several specific changes in programmes can be associated with them: Indonesia's full commitment to smallpox eradication followed the 1967 meeting in Thailand; agreements to grant national surveillance and vaccination teams free passage across specified international borders, a hitherto unprecedented occurrence, followed the 1968 conference sponsored by CDC in Côte d'Ivoire and the 1973 meeting in Ethiopia; and India's decision to adopt the surveillance-containment strategy and to undertake an intensified programme followed the 1972 meeting in New Delhi.

### Use of the Mass Media

The Smallpox Eradication unit staff actively sought publicity for the programme in national and international media, believing that it was important to make what was happening in the programme widely known to potential donors and to those in the endemic countries. For many sectors of

government, this was a natural and logical approach but there was then, both in WHO and in many countries, a reluctance on the part of physicians and other health personnel to meet representatives of the mass media or to use the media except to convey traditional health education messages. The very small staff and limited programme of WHO's Division of Public Information at that time was a reflection of this attitude.

The publication of the semi-annual summaries of progress in smallpox eradication in the *Weekly epidemiological record* provided suitable occasions for press conferences, as did the occurrence of the last cases of smallpox in large countries and the certification of eradication in each of the countries and Regions. Efforts to obtain publicity were not without their embarrassing moments, however, the most awkward occurring on 14 October 1975, when Henderson, then on a visit to New York City, announced at a press conference that 8 weeks had elapsed since the last case of smallpox in Asia and, in view of the extent and effectiveness of surveillance, confidently stated that the last case of variola

major had been seen. Only 4 days later, however, another outbreak was found in Bangladesh (see Chapter 16).

As the programme progressed, increasing attention was given to contacts with the media (see Plate 10.16), particularly as the need for voluntary contributions became more urgent. Geneva was not so important a news centre as New York, in which there were more correspondents from many more countries. Fortunately, WHO maintained a small liaison office at the United Nations in

New York with two public information officers, Ms Joan Bush and Mr Peter Ozorio, who were particularly effective in interesting the media in the programme. Among the unique ideas which they fostered were transatlantic press conferences, one in 1974, in which science writers and correspondents in New York and Washington interviewed Henderson in Geneva, and a second, in 1975, in which science writers in London and Dr Nicole Grasset, the adviser on smallpox eradication in the South-East Asia Region,

**Plate 10.16.** **A:** Lawrence K. Altman (b. 1937), correspondent for the *New York Times*, had been an epidemiologist with the measles control programme in western Africa in 1964–1965. **B:** James Magee (b. 1929) was the public information officer with the Smallpox Eradication unit, 1978–1980. **C** and **D:** Joan Bush (b. 1928) and Peter Ozorio (b. 1928) served in New York as public information officers attached to the WHO Liaison Office with the United Nations.

answered questions from New Delhi, India.

Especially extensive and helpful press coverage was provided twice during the programme—in 1974 and 1978. The first related to epidemic smallpox in India during

1974, the most critical year for smallpox eradication in Asia (see Chapters 15 and 16). In that year, a large number of correspondents, who had come to India to report on the detonation for the first time of an Indian

### Publicizing the Programme

Special issues of the WHO magazine *World health*, stamps and medals served to publicize the programme and its accomplishments. In addition to the special issues of *World health* in 1965 on the theme "Smallpox: Constant Alert" and in 1975 on "Smallpox: Point of No Return", a third special issue was published in October 1972, with the slogan "Smallpox: Target Zero" (Plate 10.18). It coincided with the launching of what was termed the "final phase" which, at that time, was expected to result in eradication by the summer of 1974. As its introduction stated: "The global eradication programme this year, for the first time, extends into every state and province of every country where the disease exists. The final phase of the campaign is beginning." Unforeseen problems, however, resulted in the final phase lasting fully 3 years longer than had been optimistically envisaged.

*World health* featured the subject of smallpox on two other covers—in October 1979, on the occasion of certification of eradication in the last of the endemic countries, and in May 1980 (see Chapter 24, Plate 24.2), when the Thirty-third World Health Assembly accepted the recommendation of the Global Commission for the Certification of Smallpox Eradication that "smallpox eradication has been achieved throughout the world" and that "smallpox vaccination should be discontinued in every country except for investigators at special risk".

Postage stamps and cachets on the theme of smallpox eradication and vaccination were issued by many different governments between 1965 and 1980, as illustrated in Plates 10.19–10.22. The largest number were produced in 1978, the year after the world's last outbreak, in response to a recommendation by the Universal Postal Union to its member governments that smallpox eradication should be a principal philatelic theme. In 1978, too, the United Nations issued special stamps and silver medals in recognition of the achievement (Plate 10.23).

In some countries, stamps echoed the 1965 World Health Day theme of "Smallpox: Constant Alert"; several countries of western and central Africa issued stamps between 1968 and 1972 during the course of the programme for smallpox eradication and measles control, most of which featured pictures of the jet injector; and Guinea, on completion of its WHO-supported smallpox vaccine production laboratory, issued a full set of stamps depicting various stages in the vaccine production process (see Chapter 11, Plate 11.10).

In commemoration of the declaration at the Thirty-third World Health Assembly of the global eradication of smallpox, all delegations were presented with a set of medals as mementos (Plate 10.23); these bore inscriptions in the six official languages of WHO—Arabic, Chinese, English, French, Russian and Spanish.

nuclear device, discovered that the recorded incidence of smallpox was the highest for 20 years and reported this as well. Also in 1974, a series of articles published in the *New York Times* by Dr Lawrence Altman, who was on an extended tour of India and Bangladesh, vividly documented the magnitude of the effort being made and, in turn, stimulated the interest of other publications. The consequent international publicity brought greatly increased and badly needed support for the programme from senior government officials and played an important role in obtaining additional voluntary contributions. In 1978, world-wide press coverage followed the

occurrence of 2 laboratory-associated smallpox cases in Birmingham, England (see Chapter 23) at a time when the Smallpox Eradication unit was having difficulties in persuading laboratories to destroy or transfer their stocks of variola virus. As a result, national governments took a special interest in the matter and compliance followed rapidly throughout the world.

As the goal of global eradication was approached, it was important for a quite different reason to publicize the status of smallpox and its anticipated demise. With the achievement of eradication, it would be possible to discontinue routine smallpox

**Plate 10.18.** The smallpox eradication programme was presented in several issues of *World health*, an illustrated magazine published in many languages by WHO and directed to the general public.

**Plate 10.19.** Postage stamps depicting smallpox eradication activities issued by western and northern African countries between 1968 and 1975. The Libyan stamps at the lower right take up the theme of World Health Day, 7 April 1975: "Smallpox: Point of No Return".

**Plate 10.20.** Postage stamps issued in 1978 by Brazil, Egypt, Iraq, Ireland, Kuwait and Lesotho to celebrate the eradication of smallpox.

**Plate 10.21.** Postage stamps issued in 1978 by Malaysia, Maldives, Mozambique and Nigeria to celebrate the eradication of smallpox.

**Plate 10.22.** Postage stamps issued in 1978 by the Philippines, Senegal, Togo, Tunisia and the United Nations to celebrate the eradication of smallpox.

**Plate 10.23. A:** A proof set, presented to the Director-General of WHO by the United Nations, of sterling silver medals struck to celebrate the eradication of smallpox. The medals were issued on 31 March 1978 in the 5 original official languages of the United Nations in conjunction with the stamps shown in Plate 10.22. **B:** In May 1980, when the Thirty-third World Health Assembly had formally declared the global eradication of smallpox, each delegation to the Health Assembly received a set of commemorative medals in the 6 official languages of WHO.

vaccination as well as the use of international smallpox vaccination certificates. Vaccination was a long-established procedure, however, and it was unlikely to be discontinued unless both health officials and the public were aware of what had been accomplished and had confidence in that achievement. A public information officer, Mr James Magee, was therefore recruited to work full time with the Smallpox Eradication unit in Geneva.

Accounts of the progress made in the Intensified Programme appeared regularly in newspapers and magazines around the world, documentary films were made by the public broadcasting service in the USA and by Japanese television, and many countries issued special stamps; commemorative medals were also struck. Eventually, the press coverage became sufficiently extensive to cause one correspondent to write in *Science* (Wade, 1980) that "WHO has found numerous occasions on which to announce the eradication of smallpox. Another such announcement, issued with some new degree of bureaucratic solemnity, is due to emerge on 12 May. Experts consider that only definitive action by the Nobel Peace Prize committee can break the chain of transmission". However, despite numerous newspaper and magazine articles in countries throughout the world and in publications as diverse as *World health*, *National geographic*, *Reader's digest*, the *Encyclopaedia Britannica* and *Scientific American*, many persons of wide reading suggested to smallpox eradication staff that the achievement was too little known and that more should have been written about it.

### INTERNATIONAL SUPPORT IN CASH AND IN KIND

One of the most difficult problems was that of ensuring adequate international support for the national programmes, whose needs changed, often substantially, from year to year. In the original plan presented by the Director-General to the Nineteenth World Health Assembly in 1966, four sources of support were envisaged: (1) the WHO regular budget which, in 1967, included US\$2.4 million specifically earmarked for smallpox eradication; (2) contributions to the WHO Voluntary Fund for Health Promotion, Special Account for Smallpox Eradication, which the donor could make either in

cash or in kind and which, if desired, could be assigned to a specific project or country; (3) bilateral contributions; and (4) contributions from other international agencies.

The Director-General's report to the Nineteenth World Health Assembly (World Health Organization, 1966b) had forecast a need for US\$48.5 million in international assistance for a 10-year programme (1967-1976), of which one-third was expected to be provided by the WHO regular budget, the balance having to be obtained from the other sources. Ultimately, international assistance from 1967 to 1979, when eradication was certified, amounted to some US\$98 million, of which US\$34 million came from the WHO regular budget.

Of the expected sources of support, funds from the WHO regular budget were of particular importance because they could be used wherever required and for any appropriate purpose, including personnel and travel costs, the purchase of supplies and equipment, and local operational expenses—e.g., for petrol, vehicle repairs and living allowances for national staff. These funds served to complement voluntary contributions and national resources, which sometimes provided only partial support for a country programme. In programmes in western and central Africa, for example, national governments paid staff salaries and the USA provided all other needed resources except funds for the purchase of petrol and for vehicle repairs. Comparatively small sums from the WHO regular budget for "local costs", as they were termed, enabled governments in this region to undertake eradication programmes.

Undesignated gifts of cash to the WHO Special Account for Smallpox Eradication could likewise be used for any necessary purpose and had the further advantage that balances could be carried forward from year to year. Few undesignated gifts of cash were received, however, the contributions until 1974 being primarily in the form of vaccine. During the period 1974-1978, several donors made substantial cash contributions to the voluntary fund, almost all of which were designated for use in specific countries.

Significant bilateral support was provided by the USA and the USSR, the former providing almost all international assistance for programmes in western and central Africa, and the latter supplying very large quantities of vaccine to several Asian countries and to

some in Africa. International agencies other than WHO had been expected to provide substantial assistance but little was received.

Except for the first 2 years of the Intensified Programme (1967-1968), when activities in many countries were only just beginning, the inadequacy of resources presented a continuing problem. Headquarters, regional and national staff expended considerable time and effort in attempts to obtain assistance. Frequently, however, it was found that the available funds were sufficient to sustain activities for only a few months. The difficulties, even as late as 1975, may be illustrated by an estimate prepared in July of that year of the requirements and availability of resources for 1975 and the 2 subsequent years in addition to those provided under WHO's regular budget (Table 10.3).

It had been hoped that, when it became apparent that global eradication was feasible and perhaps within reach, funds would be more readily forthcoming. Even during 1976, however, with known smallpox confined to Ethiopia, the problem did not diminish, as is shown by a memorandum of 17 February 1976 from Henderson to the Director of the WHO Regional Office for the Eastern Mediterranean:

"I concur entirely with you in regard to your appraisal of need for a WHO epidemiologist to be attached to the smallpox eradication programmes in Sudan and Somalia ... I fear that there may be unknown foci ... which may yet cause real problems ... However, I'm very concerned about our funding position ... Frankly, at this time, we simply don't have the money to fund the Ethiopian programme beyond April or May and, at the same time, funds for Bangladesh will be exhausted at the end of March. One would have expected all sorts of support at this time but we are simply not getting it."

### The WHO Regular Budget

Funds from the WHO regular budget were an important component of international assistance but it was difficult to apply them optimally in the context of ever-changing global needs. Their allocation by WHO Region and by country should ideally have taken into account both relative need and the global strategy, but this was difficult given WHO's decentralized structure and administrative procedures.

The WHO budget process was best suited to the support of a diverse array of national

Table 10.3. Estimated requirements and available resources as at July 1975, in addition to those provided under the WHO regular budget, 1975-1977 (US\$)

Year	Amount needed	Available	Deficit
1975	1 975 000	1 445 000	530 000
1976	1 560 000	345 000	1 215 000
1977	1 450 000	345 000	1 105 000

projects, which were usually small and had financial requirements that were reasonably predictable from year to year. The Director-General's annual budget, developed over a 2-year period, was a composite of proposals prepared separately by regional directors and Headquarters units and based, in part, on requests for assistance received from countries. Each regional director drew up a detailed budget specifying personnel and other costs for each project in each country and in the regional office. These project proposals were usually not reviewed by the relevant technical units at Headquarters, which similarly submitted detailed budget proposals of their own, broken down by permanent staff and consultant costs, as well as proposed expenditures for travel, meetings and other items. Following a review of the proposals by the Director-General and the assistant directors-general, an overall proposed programme and budget for the entire Organization was set out in detail for consideration by the Executive Board at its January session and by the World Health Assembly, which was usually convened in May—7 months before the beginning of the next financial year. The Smallpox Eradication unit had no indication as to the total allocations available for smallpox eradication each year until the budget volume was distributed.

The budget was almost invariably approved by the Health Assembly as presented, after which each regional director could transfer WHO regional resources from one project to another as need and opportunity presented. Funds could be transferred from one region to another only by the Director-General, but such transfers were seldom made.

In 1967, more than 90% of all the funds voted for smallpox eradication by the Health Assembly were allocated by the Director-General to the 4 regions in which endemic smallpox was then present (Table

10.4), only a small amount (about 8%) being provided to support Headquarters or inter-regional activities.

Because of the nature of the budget process, the Smallpox Eradication unit decided that the best way of achieving the optimum allocation of resources was through close collaborative planning with regional office staff. If this could be achieved, it was believed that a consensus on needs and priorities could be reached which would be reflected in annual budgets, and it would be possible to provide up-to-date information to regional directors so that transfers of funds could be made where required. Thus, each year, a planning meeting was scheduled which was attended by the officer responsible for smallpox eradication in each regional office together with senior Smallpox Eradication unit staff. Although it was usually possible to reach a consensus as to priorities and allocations of resources, the subsequent execution of agreed plans ranged from excellent to indifferent.

During the first 2 years of the Intensified Programme, the full utilization of appropriated funds was a major concern. At the Nineteenth World Health Assembly, in 1966, a number of delegates had proposed a budget of US\$1 million for smallpox eradication, since they doubted whether the Organization could fully utilize US\$2.4 million. Although the Director-General had assured them that the larger amount could be well used, this was, in fact, not easily accomplished. Before funds could be obligated, country plans and lists of the supplies and equipment needed had to be drawn up. With full-time advisers for smallpox eradication in only 2 of the WHO regions, and those not the most seriously affected, the task was not easy. Yet, if the funds were not fully expended, it would reflect poorly on the Organization. In 1967 and 1968, a lengthy correspondence was carried on with each of the WHO regions concerned, analysing and reanalysing budgets and obligations and repeatedly urging the regions to develop agreements and obligate funds as soon as possible.

The full obligation of allocated funds would have been facilitated by the procurement of a reserve fleet of vehicles, to be dispatched as they became needed by countries. This was a practice followed by UNICEF and one which would have alleviated serious delays in starting programmes, which

Table 10.4. Director-General's budgetary allocations for smallpox eradication for 1967 and estimated actual expenditure (US\$)

Region	Budget allocations for smallpox	Estimated actual expenditure
Africa	658 428	460 090
Americas	629 000	742 063
South-East Asia	815 030	295 281
Europe	0	0
Eastern Mediterranean	246 706	573 999
Western Pacific	2 000	55 831
Headquarters and Interregional	210 640	268 552
Total	2 561 804	2 395 816

were often caused by 12-18-month delivery times for vehicles. A proposal to this effect, however, was not accepted.

In 1967, plans were quickly developed in the Region of the Americas and the Eastern Mediterranean Region but far less was accomplished in Africa and South-East Asia. As the year progressed, it became apparent that the funds committed in these latter regions would fall substantially short of those allocated. This problem, however, was solved in a manner that served indirectly to provide the Smallpox Eradication unit with added discretionary resources for emergency needs. Towards the end of 1967, the Regional Director for South-East Asia was persuaded to release funds allocated for use elsewhere and the Director-General approved the transfer. Some were transferred to the Regions of the Americas and the Eastern Mediterranean and some were used for the purchase of large numbers of the new bifurcated needles and jet injectors. The subsequent ability to dispatch bifurcated needles and jet injectors (as well as vaccine) promptly to countries in need was of great help in carrying out programme activities. The Regional Director for Africa chose not to release his unobligated funds and, in December, at the end of the financial year, they were returned to Headquarters. Fortunately, however, it proved possible to recover them for the programme, thanks to the Division of Budget and Finance. Cash contributions to the WHO Voluntary Fund for Health Promotion's Special Account for Smallpox Eradication had not been large, but a moderate sum had accumulated by 1967. In that year, virtually all these funds had been spent on travel, consultants and training materials. The unobligated funds from the African Region were used to cover these

expenditures, and the cash balance in the special account was restored and carried forward to the following year. Almost every year thereafter unobligated funds from the regions enabled the cash balance in the special account to be largely restored, thus providing a small but immensely valuable cash reserve to supplement the meagre discretionary funds otherwise available for smallpox eradication through Headquarters accounts.

By 1969, most countries had begun eradication programmes and the problem of lack of funds replaced that of utilizing budgeted allocations. As Henderson wrote to the regional smallpox adviser in the Americas (21 February 1969):

"I am concerned about the problem of money this year for I am afraid we will be very hard pressed indeed. We could use substantially more in the African Region; the Eastern Mediterranean Region has requested some additional [funds] ... and the South-East Asia Region, if the Indian programme accelerates as expected, could use everything we have. I am afraid the honeymoon is over with respect to finances."

It was also pointed out that Brazil, the only endemic country in the Region of the Americas, had already received substantial resources, including funds released in 1967 by the South-East Asia Region, and it was suggested that the Region of the Americas might reciprocate by releasing some of its funds for use elsewhere. However, such transfers of funds were not customary and this proposal was rejected, as were similar subsequent ones.

To achieve a more appropriate distribution of funds, the next best approach seemed to be to attempt to change the regional allocations from year to year to reflect more accurately the relative balance of needs in the different regions. The first allocations, in 1967, had necessarily been arbitrary ones, since it had not been possible at that time to make accurate estimates of need by region. Up to 1970, the allocations remained essentially unchanged but, by then, it was increasingly apparent that far less would be required in the Americas during future years but far more in Asia and Africa and that a reapportionment based on longer-term requirements was needed. Throughout 1970, Smallpox Eradication unit staff worked closely with those in the regions to reach a consensus on future needs. Towards the end of the year, however, the unit was informed that proposals based on

these analyses would not be approved by the Director-General. Although the exercise had proved futile, it was hoped that it might still be possible at least to reduce the allocation to the Americas and to increase it in other regions. In a memorandum (dated 30 December 1970) to his Assistant Director-General, Henderson pointed out:

"Plentiful funds are available in the Region of the Americas as confirmed in discussions in Washington during December ... all concerned feel confident that smallpox transmission in the Americas will be interrupted in 1971. It is proposed that smallpox eradication funds be used to strengthen surveillance activities [in the Americas] ... However, even if gilt-edged support is provided to this enterprise, it is agreed that it would be difficult to expend more than \$250-300 000 per year [of a budgeted US\$569 000]."

The proposed change in allocation was discussed with the Regional Director for the Americas, who agreed with the budget analysis but pointed out that he needed more funds for malaria eradication and asked for some sort of trade-off so as to maintain his regional budget at a more constant level. The Director-General decided, however, not to alter the regional allocations for smallpox eradication for 1971 and, from 1972, the practice of identifying a specific allocation for smallpox eradication was discontinued. This ended the efforts to develop plans for the better deployment of funds from WHO's regular budget. After 1971, it was no longer required that a prescribed minimum amount should be spent on smallpox eradication; the regional directors allocated funds from their overall allotments on the basis of their sense of the programme's priority in relation to the other needs in their regions.

When inflation is taken into account, as was customary each year in preparing WHO's overall budget, the Organization's annual expenditures for the programme up to 1976 were close to the appropriation of US\$2.4 million originally approved by the Health Assembly in 1966 (Table 10.5). However, as the number of endemic countries decreased, increasing problems were encountered in obtaining the support necessary to complete the programme and to permit certification, as is shown by a memorandum of 6 January 1975 from Henderson to the Director-General:

"We may face some difficult questions at the Executive Board in regard to the smallpox budget

which we should be prepared for. In November, a special appeal was made by the Director-General for additional funds for the smallpox programme. The importance of the programme and the high priority given to it by the Organization was emphasized. Only \$2.1 million of the \$3.3 million requested has so far been received but we know of at least five additional countries which have indicated that additional support might be forthcoming.

"The difficult problem about which questions will almost certainly be forthcoming is why the Organization cut the smallpox allocations (by 29%) if it accords the programme such high priority and is asking for special donations. The budget cuts are evident not only in the Regions but also at Headquarters.

"As the first knowledge which I had in regard to the budget levels was when I received Official Records No. 220 [Proposed Programme and Budget for 1976-1977], I find it difficult to contrive a suitable answer which might be proposed. And yet, an inappropriate response could be most damaging, as I'm sure you would agree."

Questions were asked by the Board but the budget was not changed.

### Other Types of Assistance to Programmes

As has been mentioned earlier, it was expected that two-thirds of the total costs of the smallpox eradication programme would be met by international agencies other than WHO and by voluntary contributions to governments or to the Special Account for Smallpox Eradication in the WHO Voluntary Fund for Health Promotion. In view of the level of support for smallpox eradica-

tion during 1959-1966 (see Chapter 9), this originally seemed to be an unrealistic expectation, but such contributions eventually amounted to US\$66.9 million over the period 1967-1979 (Table 10.6).

The different types of contribution are, for the most part, considered together in this section, since it is somewhat arbitrary to identify some as bilateral contributions, some as support to the Special Account for Smallpox Eradication and some as contributions by other international organizations. For example, the substantial cash contributions made by Denmark, Norway and Sweden to programmes in Bangladesh and India during 1974-1977 were provided through the special account for administrative convenience but were a part of the bilateral assistance funds already allocated for use in these countries. Similarly, support from two United Nations organs, the United Nations Emergency Operation (UNEO) in Bangladesh in 1972 and the Office of the United Nations Disaster Relief Co-ordinator (UNDRO) in Somalia in 1977, consisted of supplies and equipment provided by national governments in response to emergency appeals rather than of funds from the established budgets of these organs.

Throughout the programme, an effort was made to account for and place a cash value on the support provided by different agencies. The data as presented, however, suggest a greater precision and completeness in accounting than is, in fact, the case. Many of the contributions were in kind rather than in cash. When a contribution was provided through the Voluntary Fund for Health Promotion, the donor was responsible for

assigning a cash value to it but different donors assigned different values to the same product. For example, most vaccine was valued at US\$10-16 per 1000 doses but values as high as US\$256 per 1000 doses were assigned by some donors. The average value for all vaccine contributed worked out at US\$17 per 1000 doses, although estimates of the actual costs of vaccine production in the industrialized countries in the early 1970s were in the range of US\$30-40 per 1000 doses.

It may be noted that in several instances the amounts in Table 10.6 are different from those recorded by the Global Commission for the Certification of Smallpox Eradication in Annex 16 to its Final Report (World Health Organization, 1980). The differences are the consequences of adjustments made in the light of more recent information. In addition, Annex 16 included the value of some bilateral contributions made before 1967 (notably by the USA and the USSR) and of cash and vaccine pledged during the period 1967-1979 by India, the USSR and the Japan Shipbuilding Industry Foundation but received after 1979; these amounts have been omitted from Table 10.6.

An attempt was also made to place a cash value on the services of volunteer personnel. For accounting purposes, a figure of US\$750 per month was assigned, an estimate provided by one of the principal donor governments. This figure, as well as a number of other approximations that were made, undoubtedly understates to some degree the value of gifts in kind. All but impossible to estimate, and not included here, is the value of services provided by many local, non-governmental groups, such as the League of Red Cross and Red Crescent Societies; Kiwanis, Lions and Rotary Clubs; youth groups, such as the Boy Scouts and Girl Guides; and missionary groups. In a number of countries such groups were most helpful in organizing vaccination campaigns, mobilizing public support and, sometimes, performing vaccinations. A few contributed funds in support of local programmes, although in comparison with national and international contributions, the cash value of all such contributions was not large.

Although voluntary contributions were recognized by the Health Assembly to be an essential adjunct to the WHO regular budget, such support was difficult to obtain. Every year, Health Assembly resolutions requested

all countries to provide additional support and every year the Director-General sent letters to all Member States and to relevant international agencies, referring to the Health Assembly resolution and asking for help. Smallpox eradication programme staff regularly met potential donors at the World Health Assembly and during special visits to national capitals and embassies; special meetings of potential donors were convened; and influential national figures who were sympathetic to the programme were regularly contacted to seek their good offices in obtaining support. Despite these efforts and despite the fact that the eradication of smallpox would be of great benefit to all countries, contributions were modest at best. This may have reflected a certain scepticism as to the feasibility of eradication; however, it also reflected the fact that WHO, except for malaria eradication, had not previously been active in seeking supplementary contributions and governments were unaccustomed to making them. As Table 10.7 shows, except in respect of malaria eradication, the contributions to the special accounts that made up the Voluntary Fund for Health Promotion did not exceed US\$2 million in any year until 1968, and of all the contributions made between 1967 and 1975, 18% were for smallpox eradication.

Vaccine for the programme was obtained entirely from voluntary contributions or local production. From 1967 to 1979, 27 countries contributed 407 million doses of vaccine to the Voluntary Fund, more than 60% of this coming from the USSR. Although industrialized countries provided most of the donated vaccine, notable contributions of vaccine were also made by Argentina, Brazil, Colombia, Guinea, India, Iran, Kenya, Peru, Philippines and Thailand.

Efforts to obtain support from UNICEF and the United Nations Development Programme (UNDP) proved disappointing, although both agencies had previously given significant support to other WHO programmes, as well as some support for smallpox eradication before 1967. Between 1967 and 1972, UNICEF provided US\$427 878 for vaccine and vaccine production equipment but none thereafter—a policy reflecting its disappointment with the lack of progress in malaria eradication and its decision not to support another attempt to eradicate a disease. The possibility of support from UNDP was explored with the resident

representatives in several countries, but lack of interest, the complexities involved in developing suitable proposals and the delays in securing their approval restricted support to US\$299 344.

Between 1967 and 1970, over half of all international expenditure on smallpox eradication was met by bilateral contributions (Table 10.8), representing primarily United States support for the programme in western and central Africa and contributions of vaccine by the USSR to India and several smaller Asian countries. With the achievement of smallpox eradication in western and central Africa in 1970, support for that programme began to be phased out and India, during the early 1970s, began to rely increasingly on domestically produced vaccine. Bilateral contributions diminished proportionately, and after 1972 exceeded US\$1 000 000 only in 1974 and 1975.

Expenditure from the Special Account for Smallpox Eradication up to the end of 1973

was accounted for primarily by the distribution of donated vaccine. The amounts increased steadily over the years, reaching US\$845 150 in 1973. Two-thirds of the expenditure on smallpox eradication in 1973, however, were met by WHO's regular budget.

Contributions to the Voluntary Fund increased significantly from 1974 onwards. In the autumn of 1973, smallpox eradication activities had been intensified in Asia, but the problems encountered in India proved far more formidable than had been anticipated (see Chapter 15) and, in response to special appeals for assistance, Sweden began to contribute substantial sums to the Voluntary Fund for use in that country, amounting in total to more than US\$9 million during 1974-1976. As difficulties mounted in Bangladesh as well, Sweden, and later Norway and Denmark, joined together to provide more than US\$5 million for its programme. Substantial additional assistance for India was also provided by the Tata Iron and Steel Company of India, by Iran and by OXFAM.

In 1974, it was also possible to intensify the programme in Ethiopia, the only endemic country outside Asia, thanks to support from the United States Public Health Service, which began to make funds available for leasing helicopters, nearly US\$2 million being provided for this purpose from 1974 to 1977. AID contributed US\$3 million to the Voluntary Fund in 1976-1977 in support of the Ethiopian programme and additional assistance was provided by Australia, Austria, Finland, the Federal Republic of Germany and Japan. Finally, with the reintroduction of smallpox into Somalia in 1976 (see Chapter 22), special appeals for funds brought contributions from the USA and from UNDRP. Meanwhile, cash contributions which could be used wherever required were provided by Canada, the Netherlands, the United Kingdom, Switzerland and the Japan Shipbuilding Industry Foundation.

By 1977, the year in which the last endemic case occurred, the Voluntary Fund covered more than 70% of all expenditures; during the period of certification activities, 1978-1979, WHO regular budget allocations were sharply decreased and the coverage by the Voluntary Fund increased to 80-90%.

Although the increase in voluntary contributions from 1974 onwards coincided with a growing recognition of the feasibility of global smallpox eradication, the donations proved to be almost as difficult to obtain as in

earlier years. A review of the origin and history of each of the contributions shows that personal, often repeated, appeals by individual members of the smallpox eradication programme staff had to be made in order to obtain each contribution.

### SUPPLY OF VACCINE AND VACCINATION INSTRUMENTS

The availability at all times of satisfactory freeze-dried vaccine and vaccination instruments was essential to the successful execution of the programme. Without vaccine and bifurcated needles or jet injectors, programme staff could do nothing; with them, methods could usually be devised to deal, at least to some extent, with shortages of transport and equipment, and so sustain both momentum and morale. Because of the importance of vaccine and vaccination instruments, Chapter 11 is devoted exclusively to the subject. Here, we summarize the methods used to ensure that both were readily available to all endemic countries and to those adjacent to them.

#### Vaccine Requirements

It had originally, but erroneously, been assumed that the provision of adequate quantities of suitable freeze-dried vaccine would not present a major problem. It was believed that, for most endemic countries, if

sufficient vaccine were not already available, it would either be provided in the form of bilateral contributions or soon be produced in the endemic countries themselves. Additional requirements would be met through contributions made through the Voluntary Fund for Health Promotion, the pledged annual contribution of 25 million doses by the USSR being considered almost sufficient for this purpose.

From what was known in 1967, adequate supplies of vaccine appeared to be available. In the Americas a number of laboratories were already producing freeze-dried vaccine and an agreement was signed by the Pan American Health Organization with Connaught Laboratories of Canada to provide for continuing consultation, the training of technicians and the monitoring of vaccine throughout that region. It seemed, therefore, that this region was already self-sufficient, or soon would be. In the African Region, the programme in western and central Africa was being carried out with the assistance of the USA, which provided the necessary vaccine to 20 countries. In virtually all other countries, some type of vaccination programme was in progress and it was assumed that many had already obtained satisfactory vaccine from some source, although it was recognized that additional vaccine would be required if the programmes were to be intensified. In the South-East Asia Region, only Nepal and possibly Indonesia among the endemic countries appeared to require vaccine. India's needs were being met by domestic production and bilateral contributions from the USSR.

Table 10.8. International expenditure on smallpox eradication, 1967-1979 (US\$)

Afghanistan and Burma were also receiving vaccine from the USSR. In the Eastern Mediterranean Region, Pakistan was thought to be producing sufficient vaccine for its own needs in a laboratory in Dhaka, and the quantities required for Ethiopia, Somalia, the Sudan and Yemen were thought not to be great.

In 1967, a detailed survey of the amount and quality of vaccine being produced throughout the world revealed that the situation was much less satisfactory than had been thought. It was discovered that much of the vaccine then in use was produced by laboratories which did not test it for stability, while some laboratories determined potency simply by vaccinating a group of young children. When tested by the 2 WHO reference laboratories, much of the vaccine from developing countries and some from industrialized ones did not meet the international standards.

During the first 2-3 years of the Intensified Programme, the provision of vaccine was not a major problem, however, because of the time required for national programmes to organize activities aimed at increasing substantially the number of vaccinations performed. Of the countries in which major programmes began in 1967, Brazil produced sufficient vaccine for its own needs and, as has already been mentioned, the countries of western and central Africa were supplied by the USA. To ensure an adequate supply of vaccine of proven potency to meet the needs of other countries, a number of measures had to be taken quickly: (1) vaccine production laboratories in endemic countries were supported by the provision of consultants, equipment and production manuals; (2) the WHO reference laboratories agreed to test all batches of vaccine produced by newly established laboratories and to participate in research and other activities which would enhance and/or simplify production methods; (3) a system of international quality control was established for all vaccine used in the Intensified Programme, whether locally produced or donated through bilateral assistance or by WHO; (4) vaccination devices were tested and introduced which used less vaccine than conventional techniques; and (5) additional contributions of vaccine were sought. As a result, sufficient vaccine of adequate quality was eventually ensured for every endemic country, although for many years reserve supplies remained perilously low.

**Plate 10.24.** Ryoichi Sasakawa, President of the Japan Shipbuilding Industry Foundation, presents a cheque for US\$500 000 to F. J. Dy, Director of the WHO Regional Office for the Western Pacific in November 1975. Masami Tanaka, Minister of Public Health of Japan, stands between them. The Foundation later increased its support to WHO for smallpox eradication to a total of nearly US\$1.8 million, the largest amount given by a nongovernmental organization.

### Support for Production Laboratories in Endemic Countries

Of the commonly used vaccines, smallpox vaccine was the easiest to produce and laboratories already existed in a number of developing countries. Priority was given to the support of laboratories in the countries with the largest populations in order both to improve the quality of their vaccine and to increase their capacity, in the expectation that voluntary contributions would meet the needs of others. A first step was to simplify and standardize production methods. The principles on which vaccine production was based were similar throughout the world, but techniques differed widely from one laboratory to another. In 1968, therefore, a meeting of the most experienced vaccine producers was convened to develop a manual (SE/68.3 Rev.2) which described in detail the optimum production procedures. Selected consultants then repeatedly visited laboratories in the endemic countries to help them to improve methods and expand capacity. On the basis of their recommendations, additional equipment and supplies were provided. Vials of seed virus for use in production, as well as

reference specimens for testing, were prepared and distributed by the National Institute of Public Health, Bilthoven, Netherlands; when the laboratories began production, batches of vaccine were tested by one or the other of the two WHO reference laboratories.

Year by year, the quantity of vaccine produced in the developing countries increased and its quality improved. In the South-East Asia Region, Burma became self-sufficient in 1969 and Indonesia in 1970; India's 4 laboratories slowly but steadily increased the quantity and quality of their vaccine. The laboratory in Dhaka likewise increased production to provide sufficient vaccine for East Pakistan, although some additional supply had to be provided during the intensified programme in 1973-1975, in what was then Bangladesh. In the African Region, support was provided to laboratories in Guinea, Kenya and Nigeria in the hope that they might serve as producers for large regions of eastern and western Africa. Kenya, by late 1968, was able to produce sufficient vaccine for several countries in eastern Africa; the laboratory in Guinea took much longer to begin production and never succeeded in producing large quantities; the laboratory in Nigeria produced only a few satisfactory experimental batches. In the Americas, most of the countries conducting programmes quickly became self-sufficient and contributed vaccine to others requiring it. Brazil, as noted above, produced sufficient vaccine for its own needs and, although many batches did not meet international standards, especially for stability, the vaccine was effective provided that it was kept cold until the time of application. The Eastern Mediterranean Region was ultimately to require the largest amounts of vaccine. Efforts to establish a laboratory in Pakistan, the country with the largest population in the region, failed because of national administrative problems, but by 1973 sufficient vaccine to meet most of Pakistan's needs was being provided by Iran. Assistance was also given to laboratories in Ethiopia, Iraq and the Syrian Arab Republic, but none of these succeeded in producing more than small quantities of satisfactory freeze-dried vaccine.

By 1971, approximately 250 million doses of vaccine were being produced annually in the endemic regions, and by then all the vaccine used in national programmes, except in Brazil, met international standards.

### Vaccine Donations

Most of the contributed vaccine was provided under bilateral agreements by the USSR, which donated more than 1400 million doses from 1958 to 1979. The USA provided more than 190 million doses, primarily to the western and central African countries, also under bilateral agreements. Contributions from other countries usually amounted to no more than a few million doses each year (see Chapter 11, Table 11.15 for the quantities contributed to WHO between 1967 and 1984). In part, this was because most industrialized countries produced their own vaccines in small national or quasi-national laboratories. Most produced little or no freeze-dried vaccine, preferring instead the glycerolated liquid vaccine, which could be dispensed more conveniently in single-dose capillaries. Although the vaccine had to be kept constantly under refrigeration, this caused little difficulty for the industrialized countries.

Except for the vaccine provided under bilateral agreements by the USSR and the USA, virtually all vaccine contributions were made through the WHO Voluntary Fund for Health Promotion. Until 1967, arranging for the acceptance and shipment of vaccine contributed to WHO was complicated and time-consuming, usually requiring 6-18 months (see Chapters 9 and 11). Several measures were therefore taken to reduce the processing interval to only 6-8 weeks. The Smallpox Eradication unit assumed responsibility for arranging for tests of batches of vaccine proposed for donation and the National Institute of Public Health, Bilthoven, agreed to examine specimens as soon as received. Specimens were shipped promptly and the results reported by telex or telephone. One obstacle to rapid processing was the requirement that vaccine titres should be determined after incubation for 4 weeks at 37 °C. When it was shown in 1969 that all vaccine batches with an adequate titre after incubation for 1 hour at 100 °C also met conventional stability tests (Arita, 1973), it was possible further to reduce the time required for testing by 4 weeks. Another problem had been that of arranging for the prompt shipment of vaccine from donor laboratory to recipient country. Many donors waited until vaccine was requested before beginning production but, even when it was available in stock, many delays occurred in arranging for international shipment. WHO

[illegible]

<sup>a</sup> From 1968 onwards, bifurcated needles started to be used for vaccination, enabling 1 dose to be used for the vaccination of 4 people. Hence numbers of doses are not necessarily the same as numbers of vaccinations performed. In addition, wastage of vaccine in the field must be taken into account. It can safely be assumed that the number of doses should be multiplied by 2 to give the number of vaccinations. Supply of vaccine by WHO was discontinued after 1980 when the eradication of smallpox was confirmed by the World Health Assembly.

**Now part of the United Arab Emirates.**

therefore decided to request that all vaccine, after testing, should be shipped to Geneva for storage in refrigerated facilities leased by WHO. With this vaccine reserve, WHO administrative staff were able to send out vaccine within 48–72 hours of receiving a request.

During 1967–1979, more than 360 million doses of vaccine were distributed to some 70 countries or organizations (Table 10.9), both vaccine and bifurcated needles being made available to all developing countries that requested them whether or not they were conducting a special eradication programme. Between 1967 and 1969, 15–20 million doses were distributed annually, a figure which increased to 30–45 million doses during the period 1970–1975. Until 1973, however, the balance between demand and available contributions remained a precarious one (Fig. 10.3). Nevertheless, no programme was suspended for lack of vaccine although, in some countries and during some periods, vaccine reserves provided enough for only 1–2 weeks of continuing operations.

Success in ensuring an adequate supply of vaccine must be attributed, in part, to the use of the bifurcated needle from 1968 onwards. Most of the vaccine was supplied in containers which provided 0.20–0.25 ml, sufficient to vaccinate 20–25 persons by conventional scarification methods and 4–5 times

that number with the bifurcated needle. For purposes of record-keeping, however, each vial continued to be regarded as containing 20–25 doses. For technical reasons vaccine could not be packaged in vials containing smaller quantities than 0.20–0.25 ml; had it been possible to do so, wastage would have been reduced, since the prescribed practice was to discard any reconstituted vaccine that remained at the end of the day.

The vaccine supply depot in Geneva proved invaluable and most vaccine was dispatched from it. In the interests of economy, however, some donated vaccine was sent direct from the producer to recipient countries. When Kenya began to produce more vaccine than it required, stocks were shipped direct from its laboratory to neighbouring countries; Iran's contributions were shipped to Pakistan; South American countries sent vaccine to one another; and Indian bilateral contributions were shipped direct to Bangladesh; Nepal and Sri Lanka in 1975–1976. Several regional offices proposed that regional depots should be established, but the small reserves available made this impracticable. When, in 1976, vaccine reserves at last began to accumulate, a second depot was created in New Delhi at the Regional Office for South-East Asia. Unfortunately, mechanical problems with the refrigeration units and frequent interruptions in the electricity supply made it necessary to close this depot down, and the international reserve of vaccine was subsequently stored by WHO in two locations in Switzerland—Geneva and Lausanne.

Fig. 10.3. Donations of smallpox vaccine to WHO: numbers of doses received and distributed, by year, 1965–1979.

### Development of Vaccination Devices

New vaccination devices used less vaccine than, and eventually replaced, the traditional scarification instruments used before 1967. Smallpox vaccination with jet injectors, first tested in a pilot project in 1965, was rapid and required only one-third as much vaccine as conventional methods. Jet injectors were widely used in three of the initial major campaigns—in Brazil (see Chapter 12), in western and central Africa (see Chapter 17) and in Zaire (see Chapter 18). However, they were little used elsewhere, partly because of the difficulty of maintaining and repairing them but mainly because the simple, effective and cheap bifurcated needle became available

in 1968, only a year after the Intensified Programme began.

The historical development of the bifurcated needle is described in Chapter 11, in which the needle itself and the containers used for sterilizing needles before use are illustrated (see Plate 11.15). Introduced in 1968 for use with a multiple-puncture technique devised by Henderson and Arita, bifurcated needles had replaced traditional methods in most countries by the end of 1968 and were in use everywhere by 1970. They cost only US\$5 per 1000 and could be reused repeatedly after sterilization. Besides conserving vaccine, they were so simple to use that a local villager could be trained in only 10-15 minutes to reconstitute vaccine and to perform effective vaccinations.

### Vaccine Practices and Complications

The WHO Handbook recommended that, in endemic and neighbouring countries, everyone, including infants, should be vaccinated. The only recognized contraindication to vaccination related to "individuals who were obviously severely acutely ill" and whose death, if it occurred, might be mistakenly attributed to vaccination. This recommendation was based on the rationale that in endemic areas the risks of complications following vaccination were far lower than those associated with contracting variola major or even variola minor. Moreover, it was recognized that most vaccinations would be performed by vaccinators who would be unable to identify conditions commonly accepted as contraindications to vaccination in non-endemic countries, such as immunological disorders, neoplastic disorders affecting the reticuloendothelial system, and treatment with corticosteroids, antimetabolic drugs or other chemotherapy.

The WHO Handbook described several possible vaccination techniques: multiple-pressure or scratch using a needle or rotary lancet, and the jet injector. An important change from conventional vaccination practice at the time was the recommendation that "the best skin preparation is none at all", and that "if the site is obviously caked with dirt, a cloth moistened with water may be used to wipe the site". This recommendation was based on a number of studies which had demonstrated that conventional methods for cleansing the skin with acetone or alcohol had

little effect in reducing the number of bacteria but could destroy or partially destroy vaccinia virus if the vaccine was applied before the liquid had dried.

During the programme, few serious complications were observed which could be attributed to vaccination. The usual response to vaccination—a pustule, with sometimes a sore arm and fever—was readily tolerated although it caused some people to refuse vaccination—for example, agricultural workers during the harvest period. Disseminated vaccinia was observed in only a few patients. Cases of post-vaccinial encephalitis, a far more serious complication, undoubtedly occurred but because of the large number of prevalent illnesses which caused cerebral symptoms (e.g., malaria), it was difficult to know whether cases of encephalitis-like illness were complications of vaccination or were due to other causes. An unusual group of complications occurred in Ethiopia among nomads of the northern Ogaden desert, a number of whom, following primary vaccination, developed a deep, non-pustular craterous lesion at the vaccination site which penetrated as deep as the muscle fascia. All those affected reported that they had applied the ashes of a thorny shrub to the lesion. Efforts to interest pharmacologists in this phenomenon were unsuccessful but the problem ceased when a sulfa powder was distributed and the nomads were advised to use this instead of the ashes.

### SURVEILLANCE AND NOTIFICATION OF SMALLPOX CASES

Whereas, up to 1967, smallpox eradication programmes consisted entirely of mass vaccination campaigns, from 1967 onwards they also included surveillance. Little attention had been given to surveillance and the notification of smallpox cases either internationally or within countries up to that time; in the endemic countries, there were no nationally organized programmes designed to investigate and contain reported outbreaks. From 1967, however, the indicator used for measuring the progress of the programme ceased to be the total number of vaccinations and was replaced by the numbers of reported cases of smallpox and of endemic countries. Epidemiological analysis of the cases provided important information from the point

of view of the strategy and tactics to be employed and the allocation of resources.

The difficulty of explaining the concept of surveillance to programme staff and of gaining their acceptance of it was not appreciated, however, when the programme began. Mass vaccination campaigns were familiar and well understood but because they were complex to organize and execute, little time and few resources were usually available for surveillance. Incorporating into programmes what had seemed to be a simple, basic concept required much of the time and energy of the senior WHO smallpox eradication programme staff.

### The Concept of Surveillance

The concept of a nationally supervised programme for reporting and investigating smallpox cases and containing outbreaks had, as its antecedent, the disease surveillance programmes of CDC in the USA (Langmuir, 1963). Dr Alexander Langmuir, its chief epidemiologist, had fostered the concept of surveillance since his appointment in 1949. He attributed the genesis of the concept to William Farr, who had been the superintendent of the Statistical Department of the Registrar General's Office of England and Wales in the 19th century. Farr's epidemiological analysis of cases and deaths over many years and by age group, area and season, made it possible to formulate hypotheses as to the way in which diseases were spread, which in turn suggested possible control measures and enabled forecasts of future trends in disease incidence to be made.

Dr Langmuir defined surveillance as the "continued watchfulness over the distribution and trends of incidence through systematic collection, consolidation and evaluation of morbidity and mortality reports and other relevant data". He pointed out that "intrinsic in the concept is the regular dissemination of the basic data and interpretations to all who have contributed and to all others who need to know". In developing surveillance in the USA, he focused primarily on diseases for which control measures were available, beginning with malaria, sylvatic plague and leprosy, and subsequently extended it to include diphtheria, poliomyelitis and other diseases. Working with state and local health officials, he and his staff obtained detailed information about reported cases, including

confirmation of the diagnosis by laboratory study and basic data regarding age, sex, race and place of residence and, depending on the disease, information regarding vaccination status, possible place of exposure, etc. These data were regularly analysed, appropriate control measures recommended and surveillance reports prepared and widely distributed.

Henderson had worked with Dr Langmuir since 1955 and had served from 1961 to 1965 as chief of the Surveillance Section at CDC. It seemed to him only logical to endeavour to apply the principles of surveillance to the eradication of smallpox. This was stated in the Director-General's report to the Nineteenth World Health Assembly (World Health Organization, 1966b; see Chapter 9), which Henderson, as a consultant to WHO, had helped to prepare. This approach was strongly supported by Dr Raška, Director of the Division of Communicable Diseases, who had been a keen proponent of epidemiological surveillance while working in his own country, Czechoslovakia (Raška, 1964).

The concept of surveillance as applied to the smallpox programme was succinctly described in the WHO Handbook as follows:

"The primary objective of the smallpox programme is the eradication of this disease. Surveillance is thus an essential component of the programme since the term 'eradication' implies that the number of indigenous cases of smallpox reach '0'... Surveillance represents a great deal more than case reporting alone. It is composed of several components:

- (a) The routine, systematic collection of data, amplified appropriately by special field investigations and studies
- (b) The concurrent analysis and interpretation of reported data and studies
- (c) The initiation of appropriate definitive action including field investigation, epidemic control, modification of operational campaign procedures, recommendations regarding vaccination, etc.
- (d) Widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities."

### The Routine Systematic Collection of Data

A reporting network which provided for the collection of epidemiological data regarding each case of smallpox was the foundation of the system. Its goal was to ensure that each week all known cases of smallpox would be

reported by the peripheral health units in each country, through intermediate administrative units, such as districts and provinces, to national and, ultimately, to international authorities. The concept was simple, but there were formidable problems at every level in perfecting such a system.

Although this section deals primarily with surveillance at the international level, certain features and problems of national data collection systems need to be described in order to appreciate the quality of the data being provided in 1967 to WHO by national authorities in the endemic countries.

Reported cases of smallpox, which would be routinely notified if the system were functioning properly, inevitably represented only a portion of all the cases which actually occurred. The basic network of reporting units—health clinics, hospitals and dispensaries—documented only those who presented themselves for treatment. Many patients had no access to health care or did not go to health care units for fear of unwanted forcible isolation in a hospital or because they knew that there was no effective treatment. They could be discovered through searches or by field investigations of known outbreaks, but few health services undertook such activities. Even where there was complete notification of all cases seen by health units, the data provided only an indication of trends in incidence and of the geographical dispersion of the disease.

In all endemic countries, the notification networks themselves were seriously deficient. Usually, health units were supposed to provide weekly or monthly summaries of the number of patients seen, but smallpox was often only one of 25-50 different diseases that they were expected to report. Poorly supervised, overworked health staff customarily devoted little time to the preparation of lengthy reports which rarely led to any action being taken. Some regularly submitted reports to higher authorities but many did so only occasionally. In intermediate administrative units—such as states or provinces—and at national level, data were usually received and tabulated, often after extended delays, by clerical personnel whose responsibility was limited to ensuring that the data were entered accurately. Little notice was taken of whether all units reported or when they did so, and because the data were rarely used in programme operations, there was little incentive to improve the system.

All countries were expected to send to WHO weekly reports of cases of the so-called quarantinable diseases (smallpox, cholera, plague, yellow fever and typhus), and to indicate the areas in which they had occurred. Such routine reporting had been the practice since the adoption of the International Sanitary Convention of 1926, when receipt and publication of the information was the responsibility of the Health Organisation of the League of Nations, a function assumed by WHO on its foundation.

In WHO, in 1967, the receipt and tabulation of data on the quarantinable diseases was the responsibility of the International Quarantine unit, which later became the Epidemiological Surveillance and Quarantine Unit and in 1971 was renamed the unit for the Epidemiological Surveillance of Communicable Diseases; for convenience, it is referred to below simply as the "WHO quarantine unit". Reports were received direct from the countries concerned rather than through the WHO regional offices, and indicated the number of reported cases in each administrative unit, or "local area" as it was called, such as a district or county. The reports also specified which of the local areas were newly infected and which could be declared free of the disease. Each week a lengthy list of the existing and newly infected local areas in each country was published in the *Weekly epidemiological record* for each of the quarantinable diseases. In theory, this enabled quarantine officers and others concerned to determine whether or not a traveller had been in an area in which one of the diseases was present and to take appropriate measures. In practice, most health authorities recognized that reporting everywhere was deficient and usually considered the whole of a country to be infected if infection was present in any of its local areas.

The WHO quarantine unit also tabulated the number of cases reported. The data so compiled were considered to be the provisional official totals of cases, pending later receipt of annual reports from national governments. Such annual reports, when compiled and published some 3-4 years later by the WHO Division of Health Statistics, constituted the final authoritative international record of disease incidence. No attempt was made to reconcile the data in the provisional reports with those in the annual reports, and national authorities were seldom questioned as to the accuracy of the information provided.

### Changes in the International Data Collection System

The inadequacy of the routine data collection system for smallpox cases had been recognized in 1967 but not until much later did it become apparent just how inadequate it was. Smallpox eradication programme staff had assumed that, because smallpox was one of the principal diseases subject to international quarantine agreements and because most infected countries submitted weekly reports, albeit after long delays, it was one of the better-reported diseases. However, field investigations soon showed that not more than 1 case in 20 was being notified. Later, through facial pockmark surveys, it became apparent that probably not more than 1 case in 100 was being reported and, in some countries, such as Ethiopia, perhaps 1 in 1000. Despite the incompleteness of reporting, however, the notified data proved to be important from the beginning of the programme for decisions about priorities and resource allocations and for assessing progress; ultimately, they were essential in determining that transmission had been interrupted and in certifying that eradication had been achieved.

Efforts to improve the system began with the initiation of the Intensified Programme. Deficiencies became apparent almost immediately when WHO staff attached to national smallpox eradication programmes cited national data which differed from those reported to the WHO quarantine unit. When efforts were made to reconcile the two sets of figures, it was discovered that, in many ministries of health, there were two sets of data, one compiled by a statistical unit and one by smallpox eradication programme staff. The statistical unit's data were taken from routine reports submitted by states and provinces, while those of the smallpox eradication programme office were often revised to take into account additional cases discovered during field investigations, reports obtained by the staff from states or provinces which had failed to file reports with the statistical office, and information on reported cases which had been mistakenly diagnosed. It was usually of no importance to national eradication programme staff whether the statistical unit's data differed from theirs or not, since such differences had no bearing on their operations.

Through correspondence with the countries and discussions with the WHO quaran-

tine unit, WHO smallpox eradication staff sought to obtain the most complete national data available. In some instances, it was possible to obtain revised national figures extending over many months or several years, which usually showed much larger numbers of cases than those reported by the national statistical unit. The WHO quarantine unit did not take cognizance of such information because its responsibility was to compile only the current data officially reported to WHO and to maintain the registry of local infected areas. For the first three years of the Intensified Programme, two sets of data were maintained at WHO on smallpox incidence during the current and immediately preceding years. Depending on the WHO publication, sometimes one and sometimes the other set of data was used, but smallpox surveillance reports always used Smallpox Eradication unit data. In 1969, it was agreed that the Smallpox Eradication unit would assume the responsibility for all current data on smallpox cases and infected local areas, a procedure which reduced confusion and conserved manpower.

Meanwhile, through personal contact, correspondence and the publication of summaries of the smallpox situation in the *Weekly epidemiological record*, governments were urged to report more promptly and gradually began to do so. However, even as late as May 1970, reports from 5 countries were more than 4 weeks overdue and not until 1972 were reports received promptly from all the states of India (see Chapter 15). By the end of 1972, however, few reports from countries were delayed by as much as 2 weeks.

In 1970, another question arose in WHO Headquarters regarding what should constitute the authoritative international record of smallpox incidence. In that year, staff in the Division of Health Statistics observed that the numbers of smallpox cases in governments' annual summaries of disease incidence (a third data set) did not always agree with the data compiled by the Smallpox Eradication unit. Upon investigation, it was found that the differences usually reflected the fact that two sets of data had been compiled nationally. In other instances, clerical errors had been made in the annual summaries submitted, sometimes resulting, for example, in smallpox cases being reported by countries remote from endemic areas and with no known importations. These errors were quickly corrected by the governments concerned when they were

Table 10.10. World total of smallpox cases as recorded in April 1967<sup>a</sup> and as revised in 1987

Date recorded or revised	1959	1960	1961	1962	1963	1964	1965	1966

<sup>a</sup> Unpublished World Health Assembly document A20/P&B/7.

brought to their attention but such data had been accepted without question in previous years. Towards the end of 1970, it was decided that the data compiled by the Smallpox Eradication unit, based on what it considered to be the most accurate national data, should be used in WHO publications. Thus, what had once been three different sets of smallpox data in WHO became one.

The possible suppression of reports of smallpox cases by national authorities was a continuing concern, although it did not happen often. Such suppression was most marked in western Asian countries and resulted, in part, from the adverse consequences of reporting cholera cases during a recent pandemic. These reports had induced other governments to impose unwarranted barriers to trade and travel which had caused serious economic losses. Some feared that reports of smallpox might result in similar measures being taken and therefore suppressed them. Cases of smallpox, especially when they were numerous, were not easy to conceal, however, and WHO learnt about them from many sources, including embassies, travellers and persons working in international organizations. All rumours of outbreaks were followed up by WHO by telex and by correspondence and sometimes by personal visits. Even when it was certain that smallpox was present, publication of the information without official government approval was diplomatically impossible. The suppression of reports had 2 adverse consequences: it jeopardized the credibility of the programme and the eventual acceptance of global eradication; and it made it difficult for the countries concerned to mobilize health resources and community support in order to control the outbreaks. Although most health authorities eventually cooperated in reporting, 4 did not acknowledge the existence of cases until many months or years later, and 3 eventually experienced major epidemics. These are discussed in Chapter 22

(Somalia) and Chapter 23 (Iran, Iraq and the Syrian Arab Republic).

Throughout the programme, national totals of smallpox cases were corrected whenever better information became available so as to reflect more accurately the actual incidence. Data for 1967-1977 were most carefully scrutinized, but changes were also made in data for a number of years preceding 1967. For example, the data presented in this book show global totals for smallpox cases between 1959 and 1966 substantially greater than those in the report (prepared in April 1967) submitted by the Director-General to the Twentieth World Health Assembly. The totals for the years 1959-1962 are 6-20% greater and those for 1963-1966 are 34-74% greater (Table 10.10). The larger discrepancies after 1963 reflect the fact that smallpox eradication staff in most countries reviewed and revised national and state or provincial data only from 1963 or 1964 onwards.

### International Surveillance Reports

A basic precept of surveillance is, as has already been quoted from the WHO Handbook, the "widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities". Accordingly, the first of what were intended to be quarterly international surveillance reports was issued by the Smallpox Eradication unit as a mimeographed document in September 1967. It was sent to some 200 persons, principally WHO staff concerned with smallpox eradication and national programme directors. A second report was issued in December 1967 and a third prepared in March 1968. Distribution of the third report was stopped, however, by senior WHO management staff, who believed that there were too many WHO reports and therefore decided to suspend most of them pending a

full review of WHO's publication policies. Eventually, it was decided that smallpox surveillance reports should be discontinued.

The coordination of a global programme was difficult enough, but without some mechanism for disseminating information on its status and the progress being made, the task appeared impossible. The matter was discussed in WHO in a series of difficult meetings extending over 8 weeks, and it was finally decided that a brief report on smallpox could be inserted periodically into the *Weekly epidemiological record*. From May 1968 onwards, such reports were published every 2-3 weeks.

Use of the *Weekly epidemiological record* had both advantages and disadvantages. The main advantage was that it was a well-established periodical with a circulation of some 5000 copies which reached a far larger audience than was possible with the mimeographed report. The disadvantage was that it published only epidemiological data, to the exclusion of other information which the smallpox eradication programme needed to have disseminated, such as the results of tests on the bifurcated needle and techniques for its use, and reports of the deliberations of relevant expert committees and scientific groups. Moreover, the periodical was normally sent by surface mail and not all WHO and national smallpox eradication programme staff had access to it. To solve these problems, it was agreed that additional copies of the smallpox surveillance section of the *Weekly epidemiological record* would be printed and sent by air mail, together with other special reports dealing with smallpox, to the 150-200 persons concerned with the programme. Thus began the practice of a special mailing every 2-3 weeks to all WHO and senior national smallpox eradication programme staff, a practice which ensured more rapid delivery than the traditional channels of communication through the regional offices. The WHO/SE, SE and SME series of documents listed with the references at the end of this book constituted most of the papers so distributed. Accounts by field staff were seldom prepared without considerable persuasion because, for many, English was not their mother tongue and few were experienced in writing papers for publication. A promise that smallpox eradication programme staff would edit all suitable papers increased the number submitted. Although the editorial burden was staggering, the papers proved invaluable in docu-

menting useful observations made in the course of the programme and in fostering evolutionary change.

Following the incorporation of the smallpox surveillance reports into the *Weekly epidemiological record*, its editor, Dr Ian Carter, began to transform the publication itself. Once unkindly referred to as "the laundry list of infected local areas", the periodical gradually became a substantive document dealing with many diseases and reaching an increasingly wider public. With time, the smallpox surveillance reports gradually increased in length and frequently appeared on the first page, but the prominence given to smallpox eradication troubled the responsible Assistant Director-General, who felt that other important disease problems were not receiving sufficient attention. He therefore directed that the smallpox reports should be relegated more often to the inside pages. Thereafter, by tacit agreement, the smallpox surveillance report appeared on the front page of the *Weekly epidemiological record* only twice a year, when the semi-annual summaries were published.

## RESEARCH

In 1967, few administrators or scientists believed that additional research was needed or would contribute to the achievement of smallpox eradication. This was understandable. A smallpox vaccine had been available and in use for more than 150 years and the commercial production of a thermostable vaccine had been perfected. The epidemiology of the disease under many different circumstances and in many countries had been described and the feasibility of eradication had been demonstrated in a number of developing countries. The basic task, as most saw it, was administrative—primarily that of organizing programmes to deliver vaccine to the population of the endemic countries. The attitude towards research was similar to that which had prevailed when global malaria eradication began in 1955. In that programme, research had been largely abandoned until 10 years later, when, with the programme progressing poorly, it was recognized that additional tools and different strategies were required. By then, however, competent and experienced research staff had turned to other fields. It was an important

lesson, and one which those in the Smallpox Eradication unit believed should be heeded.

In 1967, little smallpox research was in progress, and only US\$20 000 were allocated in the WHO budget for the support of such research. With so few resources and with only 4 medical officers in the Smallpox Eradication unit in Geneva, WHO could not undertake a comprehensive, well-organized research programme. However, it was hoped that field staff might be able to make significant contributions and, to stimulate their interest, some 20 areas requiring research were identified in the WHO Handbook. In consequence, many field staff undertook and participated in a wide range of important studies from the beginning of the programme.

One research area was of paramount importance—to establish with certainty whether there was any natural reservoir of variola virus. Since yellow fever eradication had been thwarted by the unexpected discovery of an animal reservoir, and in the light of the suggestions then being made that there might be a simian reservoir of malaria, the question naturally arose whether there might also be an unrecognized natural reservoir of smallpox. This question was dealt with in a series of planned studies involving many different investigators and laboratories.

Substantial amounts were eventually spent in support of research by many laboratories and, although no quantitative data are available, they were far greater than the sums provided by WHO. Of especial note are the contributions of CDC in Atlanta, the Moscow Research Institute for Viral Preparations, the National Institute of Health in Japan, the Department of Virology of St Mary's Hospital Medical School in London, the National Institute of Public Health in the Netherlands, Wyeth Laboratories in the USA, the Calcutta Institute of Tropical Medicine in India, the Public Health Institute in Bangladesh, the Pakistan Medical Research Centre in Lahore and the University of Maryland School of Medicine in Baltimore, whose scientists worked in Pakistan.

In retrospect, it is unlikely that the global eradication of smallpox would have been achieved without the broader understanding of smallpox, its virology and epidemiology, which the research conducted after 1967 provided. The results of such research include: the redefinition of the epidemiology of

smallpox and because of this, a change in the strategy so as to place increased emphasis on surveillance and containment; an improved understanding of the efficacy and duration of vaccinal immunity and, as a result, changes in practices pertaining to revaccination; a great improvement in vaccine production and testing procedures; the development of a new technique of vaccination, employing a new instrument; the genetic mapping of variola and vaccinia viruses to provide new insights into the relationships of the orthopoxviruses; the discovery and characterization of human monkeypox; and the development of sample survey techniques.

The research programmes and the observations made are described in detail in the appropriate chapters of this book. For this reason, only the highlights of some of them are described here so as to place them in the context of the development of the global programme.

### A Natural Reservoir of Smallpox

From 1967 onwards, attention was focused on determining whether smallpox virus could persist in nature outside the human being. If smallpox were found to persist in an enzootic state, or if there were a closely related animal orthopoxvirus which could infect humans and whose transmission could be sustained in man, it was unlikely that smallpox could be eradicated. No less important was the question of how long variola virus could persist in nature, since this, too, had implications for the possible recurrence and re-establishment of infection in areas in which transmission had been interrupted. These problems are discussed in Chapters 2, 29 and 30.

The first review of the available data dealing with a possible animal reservoir of variola virus was published by Arita & Henderson (1968). They reasoned that, if there were a natural reservoir of variola virus, non-human primates were important candidates. As is discussed in the paper, a few reports had suggested that smallpox outbreaks did occur naturally in primates, but most of them dated from the 19th century. In view of the extent of endemic smallpox in countries in which primates were found and the paucity of reports of possible outbreaks in the present century, it seemed unlikely that primates really were a reservoir, but confirmation was

required. Also of interest was the closely related monkeypox virus, first described by Magnus et al. (1959) after an outbreak among a colony of laboratory primates and subsequently reported in 3 other laboratories. No human infection had occurred, but because adults in close contact with the animals were few and probably well vaccinated, no conclusions could be drawn about the possible infectivity of the virus for man. To study the matter further, Arita, in 1967, conducted a survey of 26 biological institutions which handled large numbers of primates to ascertain whether other, unpublished, outbreaks had occurred, to discover the circumstances associated with such outbreaks and to find out whether there had also been human infections. Five other outbreaks among primates came to light but no human cases. Almost all the illnesses occurred in Asian species and were clinically similar to those observed when primates were experimentally infected with smallpox.

To consider the problem of monkeypox and to develop a research agenda, a meeting of investigators from 6 laboratories (the Informal Group on Monkeypox and Related Viruses) was convened by WHO in March 1969 in Moscow. Thereafter, the investigators met every 2 years to plan a wide range of studies on the experimental infections of primates and other mammals with variola and monkeypox viruses and serological surveys of primates in Africa and Malaysia. New impetus to the efforts was given by the discovery of the first human monkeypox cases in 1970, and the working group was expanded to include epidemiologists and mammalogists. Subsequently, special field surveys were initiated to define the problem; these continued up to 1986 (see Chapter 29). They provided important substantiating evidence that no mammalian reservoir of smallpox existed and that monkeypox, confined to villagers in the tropical rain forest, could not be maintained by person-to-person transmission.

A second problem was to determine whether variola virus could persist in nature on fomites such as cloth or as scabs, and cause infection in man many months or even years later. That this was a cause for concern had been suggested in studies by investigators in the Netherlands, who demonstrated the survival of variola virus in scabs for as long as 13 years (Wolff & Croon, 1968). Whether the virus was of sufficiently high titre or in a

form such that man could be infected was unknown. The possible persistence of variola virus in nature was also suggested by anecdotal accounts, dating from previous centuries, of cases and outbreaks following the exhumation of the body of a person who had died of smallpox and of cases said to have occurred in newly reoccupied houses in which a smallpox patient had died months or years before. The validity of these observations was uncertain because all had been reported from areas in which smallpox was then widely endemic. Also of concern were variolators in Africa and Asia, who were known to collect and retain scabs and pustular material for periods of a year or more.

To determine the possible risk of the persistence of viable variola virus under field conditions required many different epidemiological and laboratory studies. Laboratories in Bangladesh and India undertook to determine the duration of the viability of variola virus under different conditions of temperature and humidity. Epidemiologists were instructed to document with care the source of infection of cases, especially those in which there was a possibility of exposure to virus which had persisted in the environment. Special efforts were made to determine the source of infection of outbreaks in all countries thought to be free of smallpox. Variolators were contacted and questioned in detail about their experiences in retaining smallpox material, and variolation material was obtained from them for titration in the laboratory. The results of these studies are described in Chapters 2 and 30. Ultimately, it became clear that, even under favourable conditions of low temperature and humidity, the virus did not survive for more than a few days or weeks in a form which could induce infection, unless inoculated, as in variolation. Even in this case, variolators reported that they had difficulty in inducing infection with material retained for longer than a year.

### Epidemiological Observations

Of the many epidemiological observations, the most important were those which indicated that surveillance and containment should be accorded a much higher priority than had initially been appreciated. The first and most comprehensive of the field studies were those conducted in Pakistan and Bangladesh (then East Pakistan) during 1965-1968

and directed by scientists from the University of Maryland, USA, and the Pakistan Medical Research Council (see Chapters 4 and 14). In careful studies of the characteristics of the spread of smallpox, they showed that, even in highly infected areas, cases tended to occur in clusters rather than being widely disseminated, and that the disease spread less rapidly and less easily than was commonly believed and only through close personal contact. Moreover, during periods of seasonally low transmission, they found few continuing chains of smallpox transmission, mainly in urban areas. These characteristics suggested that the spread of smallpox could be more rapidly interrupted if greater emphasis were placed on the discovery of cases and the containment of outbreaks, especially during the season when transmission was at a low level and in urban areas. Observations in eastern Nigeria in 1967, in India in 1968, and in Brazil and Indonesia in 1969 confirmed the practicability of this approach. These observations were made known to all smallpox eradication programme field staff, but the basic concepts of surveillance and containment were slow to be accepted, having to be rediscovered and/or demonstrated in special programmes in most areas before they were incorporated into programmes.

Many other studies and observations arising from field programmes led to changes in strategy and operations (see Chapters 4 and 12-22). Among these were studies which showed that variola minor could persist for long periods among small nomadic groups, necessitating special surveillance procedures; that women in Afghanistan, confined to their houses by the practice of *purdah*, were mostly immune owing to a previous attack of the disease or to vaccination and that special vaccination programmes for them were unnecessary; and that the airborne transmission of variola virus over a distance was possible but only under exceptional circumstances and within buildings and so was not of concern. Methods were developed by which to estimate the incidence of smallpox in previous years, and special studies documented the frequency of persistence of facial pockmarks, observations which were important in deciding on the strategy for certification.

Few investigations were undertaken which required substantial laboratory support, partly because many of the studies required no more than physical observations of lesions or scars, and partly because few laboratories were

equipped to process large numbers of specimens. Studies which did involve laboratory support were conducted in Bangladesh, India, Somalia and Zaire and concerned the behaviour of other animal poxviruses (see Chapter 29) and the pharyngeal excretion of variola virus among contacts of patients (see Chapter 4).

### Vaccination Practices

Through research, not only did better vaccination instruments come into universal use but other vaccination practices also changed. Policies with regard to the youngest age for vaccination and the recommended frequency of revaccinations were changed. In most endemic countries, in 1967, primary vaccination was not given until the child had reached 3-12 months of age, and revaccination was performed every 3-5 years. The vaccination of neonates, however, had long been known to be a safe and effective practice and, in fact, had become a standard procedure in some countries of eastern Asia (Urner, 1927; Moodie & Cheng, 1962). Dr A. R. Rao's confirmation of these observations, in a WHO-supported programme in southern India, served to encourage wider acceptance of the practice, which made it easier to achieve higher levels of vaccination coverage during mass vaccination campaigns and enabled very young children to be protected during outbreak containment. That immunity following vaccination might be far more long-lasting than had been thought was suggested by field observations which showed that, even in well-vaccinated populations, 80-95% of cases occurred among those who had never been vaccinated. More precise measurements of vaccine efficacy subsequently confirmed that high levels of immunity continued for at least 10-20 years. These findings, documented early in the programme, led to a shift in the emphasis of vaccination campaigns from an effort to reach the entire population to approaches which would ensure that everyone had received primary vaccination at some time.

### Vaccine Production and Testing

In 1967, much was known about commercial methods for the production of freeze-dried smallpox vaccine and a production manual

was issued by WHO in 1968 (SE/68.3 Rev.2). Nevertheless, several studies were undertaken to examine certain aspects of the process, such as the optimum day for harvest to ensure maximum virus yield, the yields of virus produced by different strains, and alternative methods of purifying the vaccine and reducing bacterial content (see Chapter 11). Testing procedures were thought to have been standardized, but when different laboratories obtained quite different results on testing the same batches of vaccine, studies showed that slight but previously acceptable variations in technique were responsible; these were corrected. Although collaboration among potentially competing production laboratories is uncommon, this was not the case in the smallpox eradication programme. Laboratories in Canada, Czechoslovakia, the Netherlands, the USSR and the USA cooperated and shared information in solving problems, and their findings were communicated to all production laboratories.

### Characterization of the Orthopoxviruses

An examination of the similarities and differences between variola virus and other orthopoxviruses was important in assessing the likelihood that such a virus might, in some manner, mutate to a form whose virulence and transmissibility were such that infection could be sustained in man. Support for studies aimed at a more precise characterization of orthopoxviruses was provided by WHO to laboratories in London and Birmingham (England), Atlanta (USA), Tokyo (Japan) and Moscow (USSR), each of which committed substantial additional resources of its own. The importance of these studies increased with the discovery, in the early 1970s, in the Netherlands and in the USSR, of virus strains apparently isolated from animals and having characteristics indistinguishable from those of variola virus. Until the discovery of restriction endonucleases, which enabled the DNA structure of viral strains to be analysed, these analyses relied on biological markers, such as growth properties in different animals and cells and the optimum temperature for growth. The techniques were complex and time-consuming and the interpretation of the results was often uncertain. Ultimately, restriction endonuclease analyses of viral DNA proved of the greatest value. The isolates of variola-like viruses obtained

from animals in the Netherlands and the USSR were eventually shown to have been laboratory contaminants (see Chapter 29) and genetic analysis showed that it was highly unlikely that any of the large number of animal orthopoxviruses could be transformed by one or even several mutational steps into a virus which resembled variola virus.

### Summary

Even from this brief recapitulation, it is apparent that the epidemiological and laboratory research stimulated and coordinated by WHO contributed materially to the achievement of smallpox eradication. The effort was not, overall, a wholly integrated and comprehensively planned effort and was only modestly supported by WHO funds, but it was remarkably well directed towards finding solutions to operational questions and needs. Of signal importance was the ready cooperation of the investigators and their willingness to make available their papers and their data before publication. This, in turn, permitted the earliest possible application of new findings.

## STRATEGIES AND TACTICS IN THE EXECUTION OF NATIONAL PROGRAMMES

### Introduction

A survey of the approaches adopted in national vaccination campaigns and in surveillance and containment measures is provided in this section as an introduction to Chapters 12-22, which describe field operations in the various countries. The principles and practices were common to most but many aspects of the structure and method of operation of each national programme were unique, since each had to be adapted to the prevailing administrative, social, demographic and geographical conditions and each changed with time in response to experience and needs.

As has previously been described, the basic strategy for national programmes called for 2 different activities: (1) mass vaccination campaigns, assessed for both coverage and take rates by special teams; and (2) surveillance and containment of outbreaks. As infor-

mation accumulated on the extent of vaccinal immunity and the epidemiology of smallpox in the different countries, it became apparent that mass vaccination campaigns, particularly in Asia, were less important than the discovery and containment of outbreaks. Vaccinal immunity was found to be generally higher in most countries than had been expected and, in some countries, smallpox cases were so few that a comparatively simple surveillance and containment programme could serve to interrupt transmission.

Because mass vaccination campaigns were the traditional control method and were most readily accepted by national authorities, all endemic countries and many of those adjacent to them conducted such campaigns. While perhaps unnecessary in some areas, they served an important additional function in that vaccination teams, moving from village to village, were able to detect unreported cases of smallpox or to confirm its absence.

Surveillance-containment programmes, however, were frequently slow to begin, because the logistics of mass vaccination campaigns were so demanding and the techniques unfamiliar. Some programmes, adopting the tactics used for malaria eradication, deliberately delayed the commencement of surveillance until mass vaccination had been completed, an activity which they equated with the "attack phase" of the malaria programme. It was not always easy to persuade national programme staff and WHO smallpox eradication advisers that surveillance-containment operations should begin immediately and be accorded as high a priority as mass vaccination.

The importance of surveillance and containment was emphasized in discussions at the World Health Assembly and by Health Assembly resolutions in 1968 and 1969, and again by an explicit resolution of the Executive Board (EB45.R20), subsequently endorsed by the Twenty-third World Health Assembly (1970), in which the Board requested "all countries to take appropriate steps to improve further case-reporting and to adopt as an objective the immediate investigation and containment of all reported cases and outbreaks of smallpox from 1970 onwards" (World Health Organization, 1973a). Much effort was devoted to accomplishing this objective and demonstration-type programmes were organized to encourage it. Its importance was further reinforced

in numerous publications and communications. From 1969 onwards, smallpox eradication staff at WHO Headquarters recommended that surveillance-containment measures should be given priority over mass vaccination but because change was slow to come, they proposed in 1972 that all resources should be directed to surveillance-containment and that mass vaccination should be stopped. Although this proposal did not reduce the interest in mass vaccination on the part of most national authorities, it ultimately served to focus sufficient attention on surveillance and containment to permit the development of satisfactory programmes. To suggest that mass vaccination was unnecessary in any circumstances was recognized to be extreme and simplistic but it seemed necessary to do so at the time in order to alter national strategies. This was not without certain repercussions, however. By the time the emergency programme was introduced in Somalia in 1977, the principle of surveillance-containment had acquired a doctrinal quality and some WHO smallpox eradication advisers argued that it was heretical to conduct mass vaccination campaigns in any area, whatever the need (see Chapter 22).

The most important factors determining the success of all programmes were the quality of senior staff at the national level and their willingness to go into the field to see for themselves what progress was being made, to find solutions to problems and, by their example, to encourage lower-level supervisors to do likewise. In most countries, it was both traditional and accepted for supervisors, even at the lowest administrative levels, to remain in their offices. Many considered it demeaning to leave them, and those who wished to do so frequently lacked the necessary authority or transport. Supervision was customarily provided through verbal orders and written directives, and the results of programmes were assessed, if at all, through written reports, often of dubious veracity. In the smallpox eradication programmes, the supervisors were provided with transport, and WHO staff and consultants, by their example, played an important role in helping to change traditional patterns. Frequently, it was found that national and WHO smallpox eradication programme supervisors were almost the only supervisory staff to visit health programmes in the field or district centres and dispensaries. This type of frequent contact between supervisors and field personnel not only served to

resolve problems more rapidly and to redirect activities more efficiently but also proved invaluable in sustaining morale and interest.

In the following pages, the general practices followed in mass vaccination campaigns are discussed first, followed by those in the surveillance-containment programmes.

### Mass Vaccination Campaigns

#### *Objectives*

Before 1967, the smallpox eradication strategy relied entirely on mass vaccination in the belief that, when the proportion of susceptible persons in the population had been substantially reduced, transmission would cease. Until 1964, it had been assumed that this would occur when 80% of the population had been successfully vaccinated within a period of 4-5 years (World Health Organization, 1959b), an arbitrary figure with no scientific basis. Between 1959 and 1966, mass vaccination campaigns succeeded in eliminating smallpox in a number of countries, but whether 80% of the population had been successfully vaccinated is unknown as little attempt was made to assess the results of the campaigns and knowledge of the numbers of vaccinations performed is of little value because most of the vaccine used was thermolabile and lacked potency, so that many vaccinations were undoubtedly unsuccessful.

The WHO Expert Committee on Smallpox (1964) declared the figure of 80% to be insufficient and recommended that the goal should be to vaccinate 100% of the population. The only basis for this recommendation was the observation in India that smallpox persisted in some areas despite vaccinations which, in the numbers reported, were equivalent to 80% or more of the population. The Committee, however, ignored the information from field studies in India itself (later critically examined by Gelfand, 1966), which showed that the proportion *successfully* vaccinated fell far short of 80% because of the use of subpotent vaccines and the frequent revaccination of the most easily accessible groups. The proposition that smallpox could be eliminated by successfully vaccinating 80% of the population was thus discarded but on scientific evidence just as inadequate as that on which it had originally been based.

The WHO Handbook also recommended that mass vaccination campaigns should aim

at successfully vaccinating 80% of the population. The figure was an arbitrary one, intended only to indicate what could reasonably be expected in a well-conducted programme.

One can only speculate as to how many countries might have succeeded in interrupting transmission simply with an effective mass vaccination campaign reaching 80% or more of the population. However, from the authors' review of programmes conducted after 1967, it would appear that mass vaccination alone resulted, or probably would have resulted, in the elimination of smallpox in South America and most African countries but not in the densely populated countries of Bangladesh, India, Indonesia and Pakistan. Even in America and Africa, however, surveillance programmes were necessary, to provide the basis on which to be able to certify that transmission had been interrupted.

#### *Administration*

The mass vaccination campaigns were conducted by national health staff, usually with technical advice and material assistance from WHO and other agencies. A full-time programme director and unit were usually made responsible for the programme; in the larger countries, special units were also created at state or provincial levels. The programme staff were an integral part of the health ministry and worked with existing health service units, coordinating their activities whenever possible with those of other special programmes, such as those for BCG vaccination, malaria eradication and leprosy and yaws control. Their salaries were paid by the respective governments, although in some cases WHO supplemented the salaries of some senior staff to enable them to work full time in the programme. In most countries, international assistance bore the costs of all supplies and equipment as well as living allowances and travel costs for surveillance teams and the costs of petrol and vehicle repairs. After 1973, when many temporary workers began to be employed to intensify programmes in the remaining endemic countries of Asia and eastern Africa, their salaries were also met by funds from international assistance.

#### *Preparations*

The necessary preparations for a vaccination campaign could be completed within a matter

of a few weeks or a month or two, but most programmes did not begin until 6-18 months after an agreement had been signed between the government concerned and WHO. The length of the delay was usually determined by the time required to deliver the necessary vehicles, but also sometimes by a lag in the allocation of government funds for salaries. During this period, information regarding the past history of smallpox in the country was obtained, demographic data and maps were collected, and staff were selected and trained. As has already been noted, the compilation of the smallpox data available from state and provincial offices and other sources often revealed more cases than those recorded in statistical offices and officially reported to WHO. The compilation of such data made better baseline information available for use in deciding on priority areas for vaccination and in gauging subsequent progress. Except in areas in which malaria eradication programmes had been conducted, the existing maps were generally inaccurate and demographic data often at considerable variance with what programme operations later revealed. Nevertheless, such maps and data were useful as points of departure, changes being made in them as the programme progressed and additional information was obtained.

The supervisors and vaccinators for the programme were mainly health personnel who had previously been engaged in smallpox vaccination or who had been transferred from other field programmes, such as those for BCG vaccination or leprosy or yaws control, which for one reason or another had all but ceased operations. The numbers of health personnel required for the programme were not large and, because underutilization of health personnel in most endemic countries was common, it was seldom necessary for the government to hire additional staff to serve as vaccinators or supervisors. Those who served as vaccinators had usually had at least 6-8 years of education and were sufficiently literate to use forms for recording data. Illiterate vaccinators were also successfully used, especially after 1973, when the programmes were greatly intensified. Supervisors, in general, had had at least 10-12 years of education and had sometimes received additional training in the operation of health programmes.

For most smallpox eradication programmes, special training lasting 1-4 weeks

served to familiarize the staff with the nature of the programme and with their duties and responsibilities. In all but the largest countries staff numbers were sufficiently small to permit close and continuous contact between the senior national staff, the field supervisors and the vaccinators, thus facilitating supervision and a progressive improvement in performance. In larger programmes, and where the staff were widely dispersed, supervision was more difficult and the programmes were generally less effective. During the course of the programme in India over the period 1974-1977, however, an effective method was found for the supervision of large numbers of widely dispersed staff (Brilliant, 1985). A 1-day meeting of senior staff and supervisors was held every month to review performance, progress, strategy and problems. Subsequently, the supervisors and junior supervisors held a similar 1-day meeting and, finally, junior supervisors and vaccinators reviewed the progress in an area served by a health centre. Although the national programme involved more than 100 000 workers, it proved feasible to supervise activities closely and to modify and continually redirect the programme effectively.

Special activities were undertaken to interest and involve health staff based in the outpatient departments of hospitals, in health centres and in similar facilities. In group meetings and during field travel, smallpox eradication programme staff regularly discussed with them the nature and objectives of the programme, emphasized the need to report smallpox cases, and provided supplies and instruction in the proper storage and use of freeze-dried vaccine. Experience showed, however, that in most countries such health staff failed to report cases regularly, usually vaccinated very few of those who attended clinics and seldom undertook to vaccinate people living in nearby houses or villages.

Provision was made for the cold storage of vaccine (at 0-4°C) in the capital city, sometimes in refrigerators belonging to the programme and sometimes in other units used for the refrigeration of meat or vegetables and fruit. Vaccine was also kept at state and district centres in ordinary refrigerators, which were often provided by the programme, the number and location depending on the difficulties of travel and the availability of transport. The distribution system was designed so that vaccine would not be exposed to ambient temperatures for more

UNHCR / MEDECINS SANS FRONTIERES

than 30 days. In most programmes, however, the maintenance of an effective "cold chain" proved difficult and was often unsatisfactory, usually because of the mechanical failure of refrigerators, interruptions in electrical supply or lack of kerosene. Not infrequently, the vaccine was exposed to ambient temperatures for more than 30 days but because of the high titre and the stability of most vaccines, primary vaccinations were usually successful in 95% or more of the subjects concerned even when the vaccine had been exposed to such temperatures for as long as 6–9 months. Despite failures in the distribution system, unsuccessful vaccinations with properly manufactured vaccine were uncommon after 1967.

Special efforts were made to ensure that vaccination teams and health units always had on hand an adequate supply of vaccine and bifurcated needles. The instructions therefore called for orders to be submitted in advance so that supplies could be replenished well before they ran out, but the system rarely worked well; most units and many countries waited until supplies were exhausted before ordering more. The reserve supplies of vaccine and needles in Geneva, from which

deliveries could be made within 48–72 hours, helped to overcome this difficulty.

Finally, health education materials, such as posters and brochures, radio messages and other media material, were prepared. Although these were used in all programmes, such studies as were done showed that individual discussions with villagers by team leaders, vaccinators or search workers were much more effective in obtaining cooperation and participation.

After the necessary equipment had been assembled and personnel recruited, pilot projects were conducted in most countries. Because mass vaccination was comparatively simple and often familiar, they seldom lasted more than a few weeks or months and were designed primarily for training purposes rather than to test alternative methodologies.

#### *Execution of the mass campaigns*

Most mass vaccination campaigns were designed to be completed during a period of 1–3 years, depending on the size of the country and the number of personnel available. Field activities usually began in areas with the greatest population density and the

highest smallpox prevalence, thereafter moving progressively to adjoining areas. In practice, it was found best to begin the campaign in an area in which vaccination was readily accepted by the population and the logistics were simplest, and to move to more difficult areas when operational systems were well established.

Most countries used mobile vaccination teams; they varied in size but usually consisted of 2-8 persons, each team being given a vehicle. For ease of supervision and supply and to economize in transport, groups of 4-8 teams usually worked in contiguous areas under the direction of a senior health supervisor. The teams usually worked without interruption for 3 weeks, followed by 7-10 days' rest. A useful tactic, but one seldom used, was for a team of 2-3 supervisors to move from area to area and to employ local health staff to assist them. Having individuals on the team who were familiar with the people and the area and who spoke the local language enabled better vaccination coverage to be achieved. Although wider use of this approach would have been desirable, the necessary cooperation of the local health staff was usually difficult to obtain.

If work continued throughout the year, 250 days of field work were possible, but 150-200 were more usual. In some Asian countries in particular, religious and national holidays were frequent and often prolonged; in others, effective field work during the seasonal rains or the hottest months was difficult, if not impossible.

Work schedules had to take a number of factors into account. Nomads, for example, were often widely dispersed during most of the year but would congregate at certain sites to graze their animals or to assist in the harvest during a comparatively brief period. In rural areas, farmers busy in the fields avoided vaccination for fear of the resulting fever and sore arm; better coverage was therefore achieved by vaccinating during slack periods in the agricultural calendar. Special programmes had to be scheduled to vaccinate people attending religious festivals, as in the Indian subcontinent and in many Muslim countries, where thousands or even millions of people often forgathered. Programmes for refugees and migrant seasonal workers were also important. The time of vaccination also had to be taken into account. If vaccination was offered, for example, from 9 o'clock in the morning to 5 o'clock in the

afternoon, large numbers of persons were usually away from their villages—in the fields, at school or at markets. Vaccination in the early morning and in the evening resulted in better coverage but such a schedule was often difficult to arrange.

Two basic approaches to mass vaccination were employed. Throughout Africa and South America, the assembly-point system, in which many subjects for vaccination gathered at a designated site, was well accepted and therefore widely employed. In Asian countries, house-to-house visits were usually made by vaccinators, although large numbers of persons were sometimes vaccinated at places such as railway stations, ferry crossings and refugee camps.

*Assembly-point vaccination.* At an assembly point, many people could be vaccinated by a few vaccinators in a short time if the local leaders lent their support. That support was usually sought by an "advance man" attached to the mobile teams, who visited the area concerned one or more days before the team was to arrive in order to meet the leaders, explain the nature of the programme, and enlist their support in assembling the people and controlling the crowd.

Jet injectors had been expected to be of especial value in campaigns using the assembly-point method, but their potential was seldom realized. With very well organized assembly points 1000-1500 persons an hour could be vaccinated using a jet injector but it was difficult to assemble and to vaccinate so many persons for more than a few hours each day. Because the great majority of the population lived in small, widely scattered towns and villages, the travel of the teams and the preparations at each individual site took a good deal of time. In practice, a team of 2 vaccinators using jet injectors averaged only 1500-3000 vaccinations a day, much the same as the number performed by 3 vaccinators with the much simpler bifurcated needles. Thus, in most circumstances, bifurcated needles were preferred.

The assembly-point system was usually effective in obtaining coverage rates of 80% or more wherever local support was reasonably good and even higher rates when smallpox was known to be present in the area. In rural areas, the best coverage was obtained when the assembly points were so situated that no one had to walk more than 5 kilometres, and preferably no more than 2

**Plate 10.26.** An "advance man" meets with village elders in Ethiopia to demonstrate vaccination and to explain the programme.

kilometres. Otherwise, many individuals were missed, especially children who were too young to walk very far or too old to be carried over long distances. In cities and towns, assembly points were much more closely spaced.

At the assembly points, police or village leaders were needed for crowd control, especially in areas in which the people were not accustomed to orderly queuing. Special measures also had to be taken to prevent the crowds from pressing in around the vaccinators to watch what they were doing. This was usually effected by arranging for the line of people to be vaccinated to pass through a building or between specially erected fences. The information recorded about each person vaccinated was kept to a minimum. Although some health authorities insisted initially on registering each individual by name, age, sex and place of residence, they soon discovered that this made the clerical task too burdensome and that the records compiled were of little or no value subsequently. A simple vaccination tally sheet (Plate 10.27) was commonly used to record the number of vaccinations performed by age group.

*House-to-house vaccination.* In most of the endemic countries of Asia, vaccinators cus-

tomarily went from house to house, and this practice was continued throughout the programme. To many health officials, systematic and orderly house-to-house visits seemed more likely to ensure high levels of vaccination coverage than asking people to gather at assembly points. The method, however, had certain intrinsic drawbacks which generally resulted in a lower rate of coverage. Since fewer persons could be vaccinated in a day than at an assembly point, larger numbers of vaccinators were required. They were often more poorly paid, less strongly motivated and therefore less reliable than the assembly-point vaccinators. They were also widely dispersed, so that it was difficult to supervise them, or even to determine whether they had worked at all. The household members, since they did not know when the vaccinators were going to call, were often absent, and resistance to vaccination was more frequent when families were approached one by one in this manner than when they were part of a large crowd in the carnival type of atmosphere associated with the assembly-point method. During the global eradication programme, well-supervised house-to-house programmes were conducted in some high-risk areas of Asian countries, but were seldom assessed. In most areas, traditional practices continued, indivi-

dual vaccinators being assigned responsibility for populations ranging from 5000 to 20 000 but seldom vaccinating more than 25-50 persons a day. As is described in Chapter 15, the system was costly for what it achieved.

Smallpox vaccination was generally well accepted throughout the world, even among many groups with little prior contact with health services. Groups which resisted vaccination tended to make the greatest impression on programme staff and their importance was magnified by virtue of the time and energy needed to vaccinate them. The older adults, especially women, often objected to vaccination on the grounds that they were already immune, which, in fact, most were. However, for a team trying to contain an outbreak and therefore to vaccinate everyone in the area, the older women in particular were a continual source of frustration. Some orthodox religious groups objected to vaccination on principle; on several occasions this resulted in outbreaks difficult to control. However, the numbers involved were seldom large and, through religious leaders and government officials, most people could eventually be persuaded to accept vaccination. Where variolation was practised, as in the mountainous areas of Afghanistan and Pakistan and in Benin, Togo and western

Nigeria, variolators, as well as some members of the population, objected to or actually forbade vaccination. Except in the more remote areas of Pakistan, however, it was eventually possible to persuade most of them to accept it.

The largest group to resist vaccination were the Amharas of the highland plateau area of Ethiopia. To most Amharas, vaccination was unknown and neither religious leaders nor government officials were able to influence their attitudes significantly. Because only the mild variola minor form of smallpox was prevalent in the area, they did not fear the disease, even when outbreaks occurred. Many methods were used to enhance their acceptance, including that of providing drugs against other diseases after successful vaccination, but large numbers of people still refused. Fortunately, resistance was by no means universal and smallpox transmission gradually ceased in this widely dispersed population.

The simultaneous administration of one or more antigens in addition to smallpox vaccine was known to be both safe and efficacious as well as economical of transport and personnel. For this purpose, however, additional resources had to be made available for the programme and changes in operational procedures introduced. This proved possible in a number of control programmes. In

western and central Africa, measles vaccine was given to all children between 6 months and 4 years of age; in some programmes yellow fever vaccine was also given to persons of all ages; and in others, BCG vaccine was administered, usually to those aged 0-15 years. In many countries of eastern and southern Africa, both smallpox and BCG vaccines were given from the beginning of the programme and, in Afghanistan, diphtheria, pertussis and tetanus (DPT) vaccine and BCG vaccine began to be administered after smallpox transmission had been interrupted.

The question whether other vaccines might be given during the smallpox vaccination campaign did not arise in most countries, however. Up to the end of 1977, when the mass campaigns had concluded, few of the endemic countries routinely provided other vaccines because they lacked the foreign currency to buy them and little was contributed by international agencies. BCG vaccine, which UNICEF provided to a number of developing countries, was an exception. It was difficult, however, to conduct a programme for the administration of both BCG and smallpox vaccines, since the former was usually given by a more time-consuming method—intradermal injection using a syringe and needle. In Africa, vaccinators could routinely administer 500 or more smallpox vaccinations a day using bifurcated needles but only 100 or so BCG vaccinations. To give both vaccines together required either a substantial expansion in the size of the teams—difficult because of the limited transport available—or a much slower-paced programme and inevitably a delay in interrupting smallpox transmission.

To facilitate the development of combined smallpox-BCG vaccination programmes, the Smallpox Eradication unit in Geneva promoted studies of the feasibility of administering BCG vaccine with the bifurcated needle and with the jet injector. While the results obtained with the bifurcated needle were equivocal or poor, those with the jet injector were quite satisfactory. Where jet injectors were used—in Zaire and many countries of western and central Africa—the two vaccines were administered at the same time but inoculated into different arms. Except for the constant difficulty of ensuring an adequate supply of BCG vaccine, these programmes generally functioned well.

Although an effective mass campaign for the simultaneous administration of different

antigens was difficult to start, the feasibility increased as experience was gained and an administrative structure developed. It seemed logical and desirable to the WHO Smallpox Eradication unit to encourage the transformation of the programme, as smallpox began to be eliminated, into one for the provision of other antigens as well. DPT and poliomyelitis vaccines were the best candidates, as the diseases concerned posed problems in the developing countries and the vaccines were inexpensive and as yet little used. Donations of vaccine would, however, have been needed as well as additional staff at Headquarters to develop plans, mobilize resources and provide training. Efforts were made in 1970 and later to persuade senior WHO staff of the desirability of this approach, the importance of timely action increasing as one country after another became free of smallpox and began to dismantle its programme. There was, however, resistance to the development of what was seen as yet another "vertical" programme until 1974, when the Twenty-sixth World Health Assembly decided to establish the Expanded Programme on Immunization. By then, smallpox eradication had proceeded so quickly that a number of national vaccination programmes had ceased to function.

On balance, the mass vaccination campaigns were remarkably successful in most countries, high levels of acceptance and coverage being attained in almost all in 3-4 years or less. The campaigns cost most countries no more than they had been spending on their regular control measures. As the chapters on field operations will show (Chapters 12-22), the assembly-point system of vaccination did not require large numbers of national personnel and international support usually amounted to no more than US\$0.07-0.25 per head of population over the course of the programme. The mass campaigns were, moreover, politically attractive, in some areas providing an important link between the people and the government—sometimes virtually the only one.

#### *Maintenance vaccination by the health services*

At the conclusion of their mass vaccination campaigns, most countries planned for continuing programmes of maintenance vaccination to be provided by the existing health services. Health units were requested to ensure the vaccination of newborn infants

and of children at health clinics and at school entry and to undertake periodic community-wide vaccination campaigns, but the outcome was seldom satisfactory. In all countries, large numbers of people visited health units daily for treatment but the opportunity was rarely taken to vaccinate them. When health centres were inspected, vaccine was regularly found which had been reconstituted days or even weeks previously and continued in use even though stored without refrigeration. Many of the vaccinations performed were probably unsuccessful but in few centres were subjects checked to see what the results had been.

After the mass campaigns, the levels of vaccinal immunity declined steadily in almost all countries, as was documented during surveys conducted for certification purposes. Although not the intention, this proved, paradoxically, to be helpful in the certification process; with large numbers of susceptible persons, smallpox, if present, was more likely to spread and to be detected than it would in a well-vaccinated population.

#### *Assessment*

The WHO Handbook called for "a programme of continuing evaluation of coverage and vaccination take rates by an assessment agent (or team) who is administratively independent of the vaccination team". What was envisaged was a random sample survey of 10-25% of those vaccinated, to be conducted 1-4 weeks after mass vaccination had been completed in an area. The use of an assessor who reported to someone other than the vaccination team leader increased confidence in the reliability of the findings. Although other useful types of evaluation were proposed in the WHO Handbook and were used subsequently in the programme, an ongoing appraisal of this type provided the most important information for use in the quality control of the campaigns. Like surveillance, however, sample assessment was unknown to most health officials and was adopted only with reluctance. Most considered it wasteful of manpower and vehicles to create a team whose sole responsibility was to check the work of others. Many were more willing to provide sufficient personnel to re-examine the entire population and vaccinate those without vaccination scars, but this was rarely feasible or cost-effective.

Independent assessment, although not universally practised, was used to good effect in

assembly-point programmes in Brazil and in a number of African countries, as well as in the house-to-house vaccination campaign in Afghanistan. The rationale of the methods and standards deserves comment. For a reasonably accurate appraisal of the quality of work in an area to be made, a random selection of villages was important, however crudely done, otherwise the assessment teams would visit the villages that were most easily accessible by vehicle and therefore the most likely to have the best vaccination coverage. The methods used for random selection varied widely, from a sophisticated approach in Guinea, in which villages were selected within a defined sampling frame and in proportion to population, to a much simpler one in Afghanistan, in which pieces of paper bearing the names of villages in which vaccination had been performed were placed in a box and the specified number drawn at random. The method of sampling was less important, however, than the fact that sampling was done and that teams were aware that their work was regularly checked and that, if the results were unsatisfactory, more work would be required. Most took pride in being able to meet or surpass the established goals.

The assessment teams also evaluated the efficacy of the vaccine that had been used, but only in the case of primary vaccination. The primary vaccination lesion was so distinctive that there was never any question whether vaccination had or had not been successful. With revaccination, on the other hand, there were many equivocal responses among persons with partial immunity, and their interpretation differed from observer to observer. Moreover, a standard for successful revaccination was impossible to establish because of the varying levels of immunity in different areas. For primary vaccination, a successful take rate of at least 95% was established as a minimum standard, a figure which permitted a margin of error in recording and observation because take rates normally approached 100% when a satisfactory vaccine was properly applied. The assessment of results of primary vaccination only had the further advantage that the response could be evaluated 1-4 weeks after administration, rather than in the 6-8 day period required to evaluate revaccination responses. More flexible schedules for the assessment teams were thus possible. In all but a few instances, primary vaccination take rates consistently exceeded 95%; where they were found to be

lower, problems of vaccine handling or vaccine quality were usually discovered which could then be rectified.

Coverage after a campaign was measured in terms of the proportion of the population with a vaccination scar or with evidence of recent primary vaccination rather than in terms of the proportion vaccinated during the campaign. It was simpler and more reliable to inspect a person, particularly a child, for the presence or absence of a vaccination scar or lesion than to ask whether the subject had been vaccinated during the team's visit. This simplified method was feasible because vaccinal immunity was so durable in endemic areas, even after a single primary vaccination. The standard of performance originally set by the WHO Handbook was that not less than 80% of the population should show evidence of immunity, as indicated by a vaccination scar. In most programmes, levels of 90% or more were common, the highest rates being among adults and older children. With time the methodology was changed so that in most countries only children under 15 years or even under 5 years were examined, but the criterion was retained that not less than 80%, and sometimes 90%, of that age group should have a vaccination scar or lesion. This approach was operationally advantageous because children were more likely than adults to be found in or near their homes when a visit was conducted. Given that older age groups consistently had even higher levels of coverage than the younger ones, a standard requiring evidence of immunity in 80% of children effectively ensured an overall population immunity of more than 90%.

The assessment data provided information on performance, but they were also used to guide operations, which was just as important. When it was found that vaccination coverage was below standard, teams were usually required to return to the area, sometimes without the payment of travel allowances, to revaccinate the entire population.

Other forms of assessment were also employed in the mass vaccination campaigns. One, used almost everywhere, was to compare the number of vaccinations performed in an area with the estimated resident population. This provided a rough indication of the success of the campaign but an unreliable one because the available population data for small localities were often highly erroneous

and often many non-residents were also vaccinated. In some areas of western Nigeria, for example, where the number of vaccinations reported to have been performed corresponded to 80% of the population, sample surveys later showed that fewer than 40% had vaccination scars.
